KELLEY & FIRESTEIN'S

# Textbook of Rheumatology

KELLEY & FIRESTEIN'S

# Textbook of Rheumatology

Tenth Edition

**GARY S. FIRESTEIN, MD**
Distinguished Professor of Medicine
Dean and Associate Vice Chancellor, Translational Medicine
University of California, San Diego School of Medicine
La Jolla, California

**RALPH C. BUDD, MD**
Professor of Medicine and Microbiology and Molecular Genetics
Director, Vermont Center for Immunology and Infectious Diseases
University of Vermont College of Medicine Distinguished University Professor
The University of Vermont College of Medicine
Burlington, Vermont

**SHERINE E. GABRIEL, MD, MSc**
Professor and Dean
Rutgers Robert Wood Johnson Medical School
CEO, Robert Wood Johnson Medical Group
Emeritus Professor, Mayo Clinic
New Brunswick, New Jersey

**IAIN B. McINNES, PhD, FRCP, FRSE, FMedSci**
Muirhead Professor of Medicine
Arthritis Research UK Professor of Rheumatology
Director of Institute of Infection, Immunity, and Inflammation
College of Medical, Veterinary, and Life Sciences
University of Glasgow
Glasgow, United Kingdom

**JAMES R. O'DELL, MD**
Bruce Professor and Vice Chair of Internal Medicine
University of Nebraska Medical Center
Chief of Rheumatology
Department of Medicine
Omaha Veterans Affairs
Omaha, Nebraska

**Notices**

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Names: Firestein, Gary S., editor. | Gabriel, Sherine E., editor. | McInnes, Iain B., editor. | O'Dell, James R., editor.
Title: Kelley and Firestein's textbook of rheumatology / [edited by] Gary S. Firestein, Sherine E. Gabriel, Iain B. McInnes, James R. O'Dell.
Other titles: Textbook of rheumatology
Description: Tenth edition. | Philadelphia, PA : Elsevier, [2017] | Preceded by Kelley's textbook of rheumatology / Gary S. Firestein … [et al.]. c2013. | Includes bibliographical references and index.
Identifiers: LCCN 2016009254 | ISBN 9780323316965 (hardcover : alk. paper)
Subjects: | MESH: Rheumatic Diseases | Joint Diseases | Collagen Diseases | Lupus Erythematosus, Systemic
Classification: LCC RC927 | NLM WE 544 | DDC 616.7/23–dc23 LC record available at http://lccn.loc.gov/2016009254

TOR has borne the name of Dr. Kelley with pride for decades, recognizing his foresight and scholarship in creating the premier clinical and academic text in the discipline. With the passage of time, just as rheumatology has advanced, so too TOR has evolved. This has occurred driven particularly by the vision and energy of Dr. Firestein, our Editor-in-Chief. The co-editors consider it timely to acknowledge Dr. Firestein's remarkable contribution by renaming the textbook for this, its tenth edition.

Sincerest thanks to my wonderful wife, Linda, and our children, David and Cathy, for their patience and support. Also, the editorial help of our three Cavalier King Charles puppies, Winston, Humphrey, and Punkin, was invaluable.

**Gary S. Firestein**

Sincere thanks for the kind mentoring from Edward D. Harris, Jr., as well as for the support of my wife, Lenore, and my children, Graham and Laura.

**Ralph C. Budd**

To my three boys: my dear husband, Frank Cockerill, and our two wonderful sons, Richard and Matthew, for being my constant source of inspiration, love, and pride. And to my parents, Huda and Ezzat, for their love and tireless support.

**Sherine E. Gabriel**

To my wife, Karin, for her patience, understanding, and love, and to our wonderful girls, Megan and Rebecca, of whom I am so very proud and who continue to enlighten me.

**Iain B. McInnes**

Sincere thanks to my wife, Deb, for her patience and love, and to our wonderful children and grandchildren, who inspire me: Kim, Andy and Aiden, Jennie, Dan, Georgie and Niah, and Scott, Melissa, and Cecily. I also want to thank the members of my division, who continue to support me in all my efforts.

**James R. O'Dell**

The *Textbook of Rheumatology* Editors wish to extend warm words of thanks to Linda Lyons Firestein, MD, who worked tirelessly to facilitate our organizational meetings and provided magnificent hospitality and sustenance throughout.

# Contributors

**Steven Abramson, MD**
New York University Langone Medical Center
New York, New York
*Pathogenesis of Osteoarthritis*

**KaiNan An, PhD**
Emeritus Professor
Department of Orthopedic Surgery
Mayo Clinic
Rochester, Minnesota
*Biomechanics*

**Felipe Andrade, MD, PhD**
Associate Professor of Medicine
Department of Medicine
Division of Rheumatology
The Johns Hopkins University School of Medicine
Baltimore, Maryland
*Autoantibodies in Rheumatoid Arthritis*

**Stacy P. Ardoin, MD, MS**
Associate Professor of Adult and Pediatric Rheumatology
Ohio State University
Nationwide Children's Hospital
Columbus, Ohio
*Pediatric Systemic Lupus Erythematosus, Juvenile Dermatomyositis, Scleroderma, and Vasculitis*

**Anne Barton, MBChB, MSc, PhD, FRCP**
Professor of Rheumatology
Centre for Musculoskeletal Research
The University of Manchester
Manchester, United Kingdom
*Genetics of Rheumatic Diseases*

**Robert P. Baughman, MD**
Professor of Medicine
Department of Internal Medicine
University of Cincinnati
Cincinnati, Ohio
*Sarcoidosis*

# Preface

*Whither textbooks: Learning in the internet era*

The tenth edition of the *Textbook of Rheumatology* (TOR10) returns with the entire editorial team from the previous edition and a contributing group of truly outstanding experts in the field. Once again, we believe that this represents an authoritative—actually, *the* authoritative—resource for rheumatology trainees, clinicians, and researchers.

One key question that we are asked and actually ask ourselves is, "Why produce a textbook when you can log onto the internet and download a review article or original research in an instant?" Traditionalists may relish the shiny pages of a beautiful book, but this seems antiquated in the e-book era. However, we contend that a tome like TOR10 provides an entirely different experience for the reader. It is "moderated" by the editors; authors are carefully vetted, and their chapters are reviewed by multiple experts. The organization of TOR10 is also quite distinct. We do not divide a disease or topic into multiple short chapters written by several authors and covering narrow areas; instead, we purposely keep chapters broad enough to provide an integrated view of the literature. That does not mean that TOR10 chapters are broad or superficial. On the contrary, the level of scholarship is extraordinary, and the authors demonstrate their total mastery of the topic. We have continued the principle of the founding editors to provide comprehensive references so that trainees appreciate the original, classic papers in our field. The publication cycle of textbooks is longer than the rapid fire of specific scientific discoveries or the theory du jour. This offers the distinct advantage of pause for thought. Paracelsus declared the physician's greatest friend to be time. TOR10 delivers a considered appraisal over time of the evolving general concepts of rheumatology.

Even so, textbooks might seem anachronistic at this point. Not so for TOR10! We have migrated more and more to online or e-versions. While textbook paper copy distribution drifts downward, online access as measured by "clicks" has soared. These observations confirm our basic premise that our specialty still demands the content and care that goes into creating a unique resource like TOR10.

In the coming years, our book will continue to adapt to a changing learning environment. One thing that will not change, however, is the editors' devotion to bringing readers an authoritative, well-written, and readable resource that can be trusted as the "gold standard" for our specialty to help them understand the science and practice of rheumatology. See you in a few years with TOR11!

**The Editors**

CHAPTER 1

# Biology of the Normal Joint

Steven R. Goldring • Mary B. Goldring

**KEY POINTS**

- Condensation of mesenchymal cells, which differentiate into chondrocytes, results in formation of the cartilage anlagen, which provides the template for the developing skeleton.
- During development of the synovial joint, growth differentiation factor–5 regulates interzone formation, and interference with movement of the embryo during development impairs joint cavitation.
- Members of the bone morphogenetic protein/transforming growth factor-β, fibroblast growth factor, and Wnt families and the parathyroid hormone–related peptide/Indian hedgehog axis are essential for joint development and growth plate formation.
- The synovial lining of diarthrodial joints is a thin layer of cells lacking a basement membrane and consisting of two principal cell types—macrophages and fibroblasts.
- The articular cartilage receives its nutritional requirements via diffusion from the synovial fluid, and interaction of the cartilage with components of the synovial fluid contributes to the unique low-friction surface properties of the articular cartilage.

## CLASSIFICATION OF JOINTS

Human joints, which provide the structures by which bones join with one another, may be classified according to the histologic features of the union and the range of joint motion. Three classes of joint design exist: (1) synovial or diarthrodial joints (Figure 1-1), which articulate with free movement, have a synovial membrane lining the joint cavity, and contain synovial fluid; (2) amphiarthroses, in which adjacent bones are separated by articular cartilage or a fibrocartilage disk and are bound by firm ligaments, permitting limited motion (e.g., the pubic symphysis, intervertebral disks of vertebral bodies, distal tibiofibular articulation, and sacroiliac joint articulation with pelvic bones); and (3) synarthroses, which are found only in the skull (suture lines) where thin, fibrous tissue separates adjoining cranial plates that interlock to prevent detectable motion before the end of normal growth, yet permit growth in childhood and adolescence.

Joints also can be classified according to the connective tissues that are present. Symphyses have a fibrocartilaginous disk separating bone ends that are joined by firm ligaments (e.g., the symphysis pubis and intervertebral joints). In synchondroses, the bone ends are covered with articular cartilage, but no synovium or significant joint cavity are present (e.g., the sternomanubrial joint). In syndesmoses, the bones are joined directly by fibrous ligaments without a cartilaginous interface (the distal tibiofibular articulation is the only joint of this type outside the cranial vault). In synostoses, bone bridges are formed between bones, producing ankylosis.

The synovial joints are classified further according to their shapes, which include ball-and-socket (hip), hinge (interphalangeal), saddle (first carpometacarpal), and plane (patellofemoral) joints. These configurations reflect the varying functions, with the shapes and sizes of the opposing surfaces determining the direction and extent of motion. The various designs permit flexion, extension, abduction, adduction, or rotation. Certain joints can act in one (humeroulnar), two (wrist), or three (shoulder) axes of motion.

This chapter concentrates on the developmental biology and relationship between structure and function of a "prototypic," "normal" human diarthrodial joint—the joint in which arthritis is most likely to develop. Most research that has been performed concerns the knee because of its accessibility, but other joints are described when appropriate.

## DEVELOPMENTAL BIOLOGY OF THE DIARTHRODIAL JOINT

Skeletal development is initiated by the differentiation of mesenchymal cells that arise from three sources: (1) neural crest cells of the neural ectoderm that give rise to craniofacial bones; (2) the sclerotome of the paraxial mesoderm, or somite compartment, which forms the axial skeleton; and (3) the somatopleure of the lateral plate mesoderm, which yields the skeleton of the limbs.[1] The appendicular skeleton develops in the human embryo from limb buds, which are first visible at approximately 4 weeks of gestation. Structures resembling adult joints are generated at approximately 4 to 7 weeks of gestation.[2] Many other crucial phases of musculoskeletal development follow, including vascularization of epiphyseal cartilage (8 to 12 weeks), appearance of villous folds in synovium (10 to 12 weeks), evolution of bursae (3 to 4 months), and the appearance of periarticular fat pads (4 to 5 months).

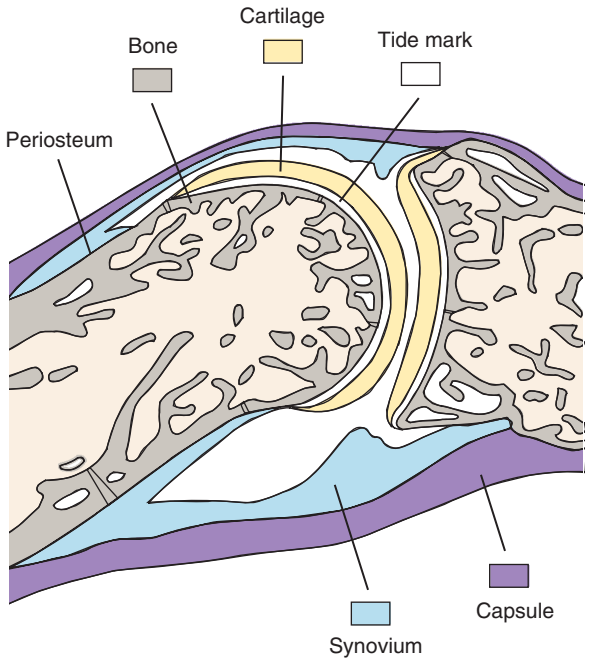

**Figure 1-1** A normal human interphalangeal joint, in sagittal section, as an example of a synovial, or diarthrodial, joint. The tidemark represents the calcified cartilage that bonds articular cartilage to the subchondral bone plate. *(From Sokoloff L, Bland JH:* The musculoskeletal system. *Baltimore, Williams & Wilkins, 1975. Copyright 1975, the Williams & Wilkins Co, Baltimore.)*

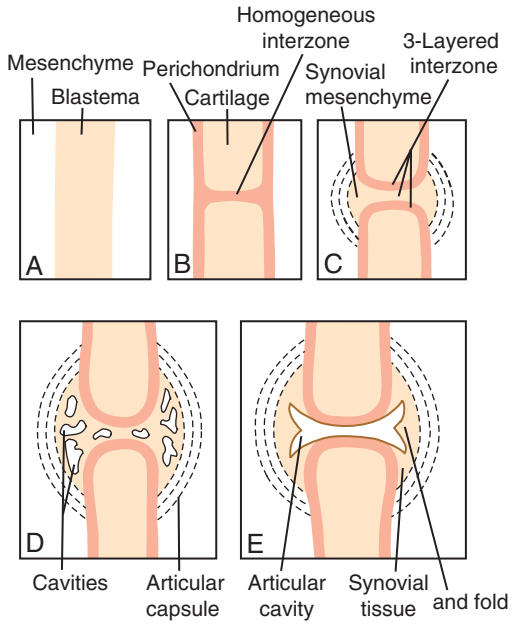

**Figure 1-2** The development of a synovial joint. **A,** Condensation. Joints develop from the blastema, not the surrounding mesenchyme. **B,** Chondrification and formation of the interzone. The interzone remains avascular and highly cellular. **C,** Formation of synovial mesenchyme. Synovial mesenchyme forms from the periphery of the interzone and is invaded by blood vessels. **D,** Cavitation. The upper limbs develop approximately 24 hours earlier than the analogous portions of the lower limbs. Proximal structures, such as the glenohumeral joint, develop before more distal ones, such as the wrist and hand. As a consequence, insults to embryonic development during limb formation affect a more distal portion of the upper limb than of the lower limb. Long bones form as a result of replacement of the cartilage template by endochondral ossification. The stages of limb development are well described by O'Rahilly and Gardner[2,3] and are shown in Figure 1-2. The developmental sequence of the events occurring during synovial joint formation and some of the regulatory factors and extra-cellular matrix components involved are summarized in Figure 1-3. The three main stages in joint development are interzone formation, cavitation, and morphogenesis, as described in detail in several reviews.[4-9]

## INTERZONE FORMATION AND JOINT CAVITATION

The structure of the developing synovial joint and the process of joint cavitation have been described in many classic studies performed on the limbs of mammalian and avian embryos.[10] In the human embryo, cartilage condensations, or chondrifications, can be detected at stage 17, when the embryo is small—approximately 11.7 mm long.[2,3] In the region of the future joint, after formation of the homogeneous chondrogenic interzone at 6 weeks (stages 18 and 19), a three-layered interzone is formed at approximately 7 weeks (stage 21), which consists of two chondrogenic, perichondrium-like layers that cover the opposing surfaces of the cartilage anlagen and are separated by a narrow band of densely packed cellular blastema that remains and forms the interzone. Cavitation begins in the central interzone at about 8 weeks (stage 23).

Although the cellular events associated with joint formation have been recognized for many years, only more recently have the genes regulating these processes been elucidated.[6,7,9] These genes include growth differentiation factor (GDF)-5 (also known as cartilage-derived morphogenetic protein-1) and Wnt14 (also known as Wnt9a), which are involved in early joint development. Two major roles have been proposed for Wnt14. First, it acts at the onset of joint formation as a negative regulator of chondrogenesis. Second, it facilitates interzone formation and cavitation by inducing the expression of GDF-5, autotaxin, lysophosphatidic acid, the bone morphogenetic protein (BMP) antagonist, chordin, and the hyaluronan receptor, CD44.[4,11] Paradoxically, application of GDF-5 to developing joints in mouse embryo limbs in organ culture causes joint fusion,[12] suggesting that temporospatial interactions among distinct cell populations are important for the correct response. The current view is that GDF-5 is required at the early stages of condensations, where it stimulates recruitment and differentiation of chondrogenic cells, and later, when its expression is restricted to the interzone.

The distribution of collagen types and proteoglycans in developing avian and rodent joints has been characterized histologically and by immunohistochemistry and in situ hybridization.[9,13,14] Types I and III collagen characterize the

matrix produced by mesenchymal cells, which switch to the production of types II, IX, and XI collagens that typify the cartilaginous matrix at the time of condensation. The messenger RNAs (mRNAs) encoding the small proteoglycans, biglycan and decorin, may be expressed at this time, but the proteins do not appear until after cavitation in the regions destined to become articular cartilage. The interzone regions are marked by the expression of genes encoding type IIA collagen by chondrocyte progenitors in the perichondrial layers, type IIB and XI collagens by differentiated chondrocytes in the cartilage anlagen, and type I collagen in the interzone and in the developing capsule and perichondrium (Figure 1-4).[15]

The interzone region contains cells in two outer layers, where they are destined to differentiate into chondrocytes and become incorporated into the epiphyses, and in a thin intermediate zone where they are programmed to undergo joint cavitation and may remain as articular chondrocytes.[8] These early chondrocytes arise from the same population, but unlike the other chondrocytes of the anlagen, they do not activate matrilin-1 expression and are destined to form the articular surface.[16] Fluid and macromolecules accumulate in this space and create a nascent synovial cavity. Blood vessels appear in the surrounding capsulosynovial blastemal mesenchyme before separation of the adjacent articulating surfaces. Although it was first assumed that these interzone cells should undergo necrosis or programmed cell death (apoptosis), many investigators have found no evidence of DNA fragmentation preceding cavitation. In addition, no evidence exists that metalloproteinases are involved in loss of tissue strength in the region undergoing cavitation. Instead, the actual joint cavity seems to be formed by mechanospatial changes induced by the synthesis of hyaluronan via uridine diphosphoglucose dehydrogenase (UDPGD) and hyaluronan synthase. Interaction of hyaluronan CD44 modulates cell migration, but the accumulation of hyaluronan and the associated mechanical influences play the major role in forcing the cells apart and inducing rupture of the intervening extra-cellular matrix by tensile forces. This mechanism accounts partially for observations that joint cavitation is incomplete in the absence of movement.[17-19] Equivalent data from human embryonic joints are difficult to obtain,[20] but in all large joints in humans, complete joint cavities are apparent at the beginning of the fetal period.

## CARTILAGE FORMATION AND ENDOCHONDRAL OSSIFICATION

The skeleton develops from the primitive, avascular, densely packed cellular mesenchyme, termed the *skeletal blastema*. Common precursor mesenchymal cells divide into chondrogenic, myogenic, and osteogenic lineages that determine the differentiation of cartilage centrally, muscle peripherally, and bone. The surrounding tissues, particularly epithelium, influence the differentiation of mesenchymal progenitor cells to chondrocytes in the cartilage anlagen. The cartilaginous nodules appear in the middle of the blastema, and simultaneously cells at the periphery become flattened and elongated to form the perichondrium. In the vertebral column, cartilage disks arise from portions of the somites surrounding the notochord, and nasal and auricular cartilage and the embryonic epiphysis form from the perichondrium. In the limb, the cartilage remains as a resting zone that later becomes the articular cartilage, or it undergoes terminal hypertrophic differentiation to become calcified (growth plate formation) and is replaced by bone (endochondral ossification). The latter process requires extra-cellular matrix remodeling and vascularization (angiogenesis). These events are controlled exquisitely by cellular interactions with the surrounding matrix, growth and differentiation factors, and other environmental factors that initiate or suppress cellular signaling pathways and transcription of specific genes in a temporospatial manner.

## Condensation and Limb-Bud Formation

Formation of the cartilage anlage occurs in four stages: (1) cell migration, (2) aggregation regulated by mesenchymal-epithelial cell interactions, (3) condensation, and (4) chondrocyte differentiation. Interactions with the epithelium determine mesenchymal cell recruitment and migration, proliferation, and condensation.[2,3,21] The aggregation of chondroprogenitor mesenchymal cells into precartilage condensations was first described by Fell[22] and depends on signals initiated by cell-cell and cell-matrix interactions, the formation of gap junctions, and changes in the cytoskeletal architecture. Before condensation, the prechondrocytic mesenchymal cells produce extra-cellular matrix that is rich in hyaluronan and type I collagen and type IIA collagen, which contains the exon-2–encoded aminopropeptide found in noncartilage collagens. The initiation of condensation is associated with increased hyaluronidase activity and the transient upregulation of versican, tenascin, syndecan, the cell adhesion molecules, neural cadherin (N-cadherin) and neural cell adhesion molecule (NCAM), which facilitate cell-cell interactions.[21,23]

Before chondrocyte differentiation, the cell-matrix interactions are facilitated by the binding of fibronectin to syndecan, thus downregulating NCAM and setting the condensation boundaries. Increased cell proliferation and extra-cellular matrix remodeling, with the disappearance of type I collagen, fibronectin, and N-cadherin and the appearance of tenascins, matrilins, and thrombospondins, including cartilage oligomeric matrix protein, initiate the transition from chondroprogenitor cells to a fully committed chondrocyte.[1,23-25] N-cadherin and NCAM disappear in

differentiating chondrocytes and are detectable later only in perichondrial cells. The differentiated chondrocytes then proliferate and become prehypertrophic when they stop proliferating and undergo the complex process of hypertrophic maturation. Whether the resting differentiated chondrocytes remain within cartilage elements in articular joints or other progenitors are the source of the articular chondrocyte has not been clarified completely.

Much of the current understanding of limb development is based on early studies in chickens and more recently in mice. The regulatory events are controlled by interacting patterning systems involving homeobox (Hox) transcription factors and fibroblast growth factor (FGF), hedgehog, transforming growth factor-β (TGF-β)/BMP, and Wnt pathways, each of which functions sequentially over time (see Figure 1-3).[11,26-29] The HoxA and HoxD gene clusters, which are crucial for the early events of limb patterning in the undifferentiated mesenchyme, are required for the expression of FGF-8 and Sonic hedgehog (Shh),[30] which modulate the proliferation of cells within the condensations.[21] BMP-2, BMP-4, and BMP-7 coordinately regulate the patterning of limb elements within the condensations depending on the temporal and spatial expression of BMP receptors and BMP antagonists, such as noggin and chordin, as well as the availability of BMP- and TGF–β-induced SMADs (signaling mammalian homologues of *Drosophila* mothers against decapentaplegic).[31] BMP signaling is required for the formation of precartilaginous condensations and for the differentiation of precursors into chondrocytes,[32,33] acting in part by opposing effects on FGF actions.[34] Growth of the condensation ceases when noggin inhibits BMP signaling and permits differentiation to chondrocytes. The cartilage formed serves as a template for formation of cartilage elements in the vertebra, sternum, and rib, and for limb elongation or endochondral bone formation.

## Molecular Signals in Cartilage Morphogenesis and Growth Plate Development

The cartilage anlagen grow by cell division and deposition of the extra-cellular matrix and by apposition of proliferating cells from the inner chondrogenic layer of the perichondrium. The nuclear transcription factor, Sox9, is one of the earliest markers expressed in cells undergoing condensation and is required for the subsequent stage of chondrogenesis characterized by the deposition of matrix containing collagens II, IX, and XI and aggrecan in the cartilage anlagen.[35] The expression of SOX proteins depends on BMP signaling via BMPR1A and BMPR1B, which are functionally redundant and active in chondrocyte condensations, but not in the perichondrium.[32] Sox5 and Sox6 are required for the expression of Col9a1, aggrecan, link protein, and Col2a1 during chondrocyte differentiation.[36] The runt-domain transcription factor, Runx2 (also known as core binding factor, Cbfa1), is expressed in all condensations, including those that are destined to form bone.

Throughout chondrogenesis, the balance of signaling by BMPs and FGFs determines the rate of proliferation and the pace of the differentiation.[28,34,37] In the long bones, long after condensation, BMP-2, BMP-3, BMP-4, BMP-5, and BMP-7 are expressed primarily in the perichondrium, and only BMP-7 is expressed in the proliferating chondrocytes.[37] BMP-6 is found later exclusively in hypertrophic chondrocytes along with BMP-2. More than 23 FGFs have been identified thus far.[38] The specific ligands that activate each FGF receptor (FGFR) during chondrogenesis in vivo have been difficult to identify because the signaling depends on the temporal and spatial location of not only the ligands but also the receptors.[39] FGFR2 is upregulated early in condensing mesenchyme and is present later in the periphery of the condensation along with FGFR1, which is expressed in surrounding loose mesenchyme. FGFR3 is associated with proliferation of chondrocytes in the central core of the mesenchymal condensation and overlaps with FGFR2. Proliferation of chondrocytes in the embryonic and postnatal growth plate is regulated by multiple mitogenic stimuli, including FGFs, which converge on cyclin D1.[40]

Early studies indicated that FGFR3 could serve as a master inhibitor of chondrocyte proliferation via Stat1 and the cell cycle inhibitor p21. More recent work has shown that FGFR3 activation downregulates AKT activity to decrease proliferation[41] and MEK activation leads to decreased chondrocyte differentiation.[42] The physiologic FGFR3 ligands are not known, but FGF-9 and FGF-18 are good candidates because they bind FGFR3 in vitro and are expressed in the adjacent perichondrium and periosteum, forming a functional gradient.[28,43] FGF-18–deficient mice have an expanded zone of proliferating chondrocytes similar to that in FGFR3-deficient mice, and FGF-18 can inhibit Indian hedgehog (Ihh) expression. As the growth plate develops, FGFR3 disappears and FGFR1 is upregulated in the prehypertrophic and hypertrophic zones, where FGF-18 and FGF-9 regulate vascular invasion by inducing vascular endothelial growth factor (VEGF) and VEGFR1 and terminal differentiation.[38,44,45]

The proliferation of chondrocytes in the lower proliferative and prehypertrophic zones is under the control of a local negative feedback loop involving signaling by parathyroid hormone–related protein (PTHrP) and Ihh.[46] Ihh expression is restricted to the prehypertrophic zone, and the PTHrP receptor is expressed in the distal zone of periarticular chondrocytes. The adjacent, surrounding perichondrial cells express the Hedgehog receptor patched (Ptch), which, upon Ihh binding, similar to Shh in the mesenchymal condensations, activates Smo and induces Gli transcription factors, which can feedback regulate Ihh target genes in a positive (*Gli1* and *Gli2*) or negative (*Gli3*) manner.[47,48] Ihh induces expression of PTHrP in the perichondrium, and PTHrP signaling stimulates cell proliferation via its receptor expressed in the periarticular chondrocytes.[28,49] More recent evidence indicates that Ihh also acts independently of PTHrP on periarticular chondrocytes to stimulate differentiation of columnar chondrocytes in the proliferative zone, whereas PTHrP acts by preventing premature differentiation into prehypertrophic and hypertrophic chondrocytes, suppressing premature expression of Ihh.[50,51] Ihh and PTHrP, by transiently inducing proliferation markers and repressing differentiation markers, function in a temporospatial manner to determine the number of cells that remain in the chondrogenic lineage versus the number that enter the endochondral ossification pathway.[46] Components of the extra-cellular matrix also contribute to regulation of the different stages of growth plate development, including chondrogenesis and terminal differentiation, by interacting

with signaling molecules and chondrocyte cell surface receptors.[52]

## Endochondral Ossification

The development of long bones from the cartilage anlagen occurs by a process termed *endochondral ossification*, which involves terminal differentiation of chondrocytes to the hypertrophic phenotype, cartilage matrix calcification, vascular invasion, and ossification (see Figure 1-3).[28,49,53] This process is initiated when the cells in the central region of the anlage begin to hypertrophy, increasing cellular fluid volume by almost 20 times. Ihh plays a pivotal role in regulating endochondral bone formation by synchronizing perichondrial maturation with chondrocyte hypertrophy, which is essential for initiating the process of vascular invasion. Ihh is expressed in prehypertrophic chondrocytes as they exit the proliferative phase and enter the hypertrophic phase, at which time they begin to express the hypertrophic chondrocyte marker, type X collagen and alkaline phosphatase. These cells are responsible for laying down the cartilage matrix that subsequently undergoes mineralization. Wnt/β-catenin signaling promotes chondrocyte maturation by a BMP-2–mediated mechanism and induces chondrocyte hypertrophy partly by enhancing matrix metalloproteinase (MMP) expression and potentially by enhancing Ihh signaling and vascularization.[54]

Runx2, which serves as a positive regulatory factor in chondrocyte maturation to hypertrophy, is expressed in the adjacent perichondrium and in prehypertrophic chondrocytes, but less in late hypertrophic chondrocytes, overlapping with Ihh, COL10A1, and BMP-6. IHH induces Gli transcription factors, which interact with Runx2 and BMP-induced Smads, to regulate transcription and expression of *COL10A1*.[55] An essential role for Runx2 in the process of chondrocyte hypertrophy is supported by the observation that the terminal differentiation is blocked in Runx2-deficient mice. A member of the myocyte enhancer factor (MEF) 2 family, MEF2C, stimulates hypertrophy partly by increasing Runx2 expression.[56] The class II histone deacetylase, HDAC4, prevents premature hypertrophy by directly suppressing the activities of Runx2 and MEF2C.[57] HDAC4 is in turn regulated by PTHrP and salt-inducible kinase 3 (SIK3).[58,59] Sox9,[60] FOXA2 and FoxA3,[61] Runx3,[62] Zfp521,[63] and peroxisome proliferator-activated receptor γ (PPARγ[64]) are also important transcriptional regulators of chondrocyte hypertrophy. MMP-13, a downstream target of Runx2, is expressed by terminal hypertrophic chondrocytes, and MMP-13 deficiency results in significant interstitial collagen accumulation, leading to the delay of endochondral ossification in the growth plate with increased length of the hypertrophic zone.[65,66]

Runx2 also is required for transcription activation of *COL10A1*, the gene encoding type X collagen, which is the major matrix component of the hypertrophic zone in the embryo and in the postnatal growth plate. Mutations in the *COL10A1* gene are associated with the dwarfism observed in human chondrodysplasias. These mutations affect regions of the growth plate that are under great mechanical stress, and it has been suggested that the defect in skeletal growth may be due partly to alteration of the mechanical integrity of the pericellular matrix in the hypertrophic zone, although a role for defective vascularization also has been proposed. The extra-cellular matrix remodeling that accompanies chondrocyte terminal differentiation is thought to induce an alteration in the environmental stress experienced by hypertrophic chondrocytes, which eventually undergo apoptosis.[67] Whether chondrocyte hypertrophy with cell death is the ultimate fate of hypertrophic chondrocytes or whether hypertrophy is a transient process that precedes osteogenesis has been a subject of debate. However, recent genetic lineage tracing studies suggest that hypertrophic chondrocytes can survive at the chondro-osseous junction and become osteoblasts and osteocytes.[68,69]

Cartilage is an avascular tissue, and because the developing growth plate is relatively hypoxic, hypoxia inducible factor (HIF)-1α is important for survival as chondrocytes transition to hypertrophy. Under normoxia, the cell content of HIF-1α, -2α , and -3α is low because of oxygen-dependent hydroxylation by prolyl-hydroxylases, resulting in ubiquitination and degradation by the proteasome. In contrast, under hypoxia, prolyl-hydroxylase activity is reduced and the α subunits heterodimerize with the constitutive β-subunit members known as aryl hydrocarbon receptor nuclear translocators (ARNTs). HIFs are transcription factors that bind to hypoxia-responsive elements (HREs) in responsive genes. HIF-2α regulates endochondral ossification processes by directly targeting HREs within the promoters of the *COL10A1*, *MMP13*, and *VEGFA* genes.[70]

Vascular invasion of the hypertrophic zone is required for the replacement of calcified cartilage by bone. VEGF acts as an angiogenic factor to promote vascular invasion by specifically activating local receptors, including Flk1, which is expressed in endothelial cells in the perichondrium or surrounding soft tissues; neuropilin 1 (Npn1), which is expressed in late hypertrophic chondrocytes; or Npn2, which is expressed exclusively in the perichondrium. VEGF is expressed as three different isoforms: VEGF188, a matrix-bound form, is essential for metaphyseal vascularization, whereas the soluble form, VEGF120 (VEGFA), regulates chondrocyte survival and epiphyseal cartilage angiogenesis, and VEGF164 can be either soluble or matrix bound and may act directly on chondrocytes via Npn2. VEGF is released from the extra-cellular matrix by MMPs, including MMP-9, membrane-type (MT)1-MMP (MMP-14), and MMP-13. MMP-9 is expressed by endothelial cells that migrate into the central region of the hypertrophic cartilage.[71] MMP-14, which has a broader range of expression than MMP-9, is essential for chondrocyte proliferation and secondary ossification, whereas MMP-13 is found exclusively in late hypertrophic chondrocytes. Perlecan (Hspg2), a heparan sulfate proteoglycan in cartilage matrix, is required for vascularization in the growth plate through its binding to the VEGFR of endothelial cells, permitting osteoblast migration into the growth plate.[72]

A number of ADAM (a disintegrin and metalloproteinase) proteinases are also emerging as important regulators in growth plate development. For example, ADAM10 is a principle regulator of Notch signaling, which modulates endochondral ossification via RBPjk in chondrocytes[73] and promotes osteoclastogenesis at the chondro-osseous junction by regulating endothelial cell organization in the developing bone vasculature.[74] ADAM17 is the critical proteinase mediating cellular shedding of TNF but also the epidermal

growth factor receptor (EGFR) ligands, including TGF-α. The EGFR signaling pathway induced by EGF and TGF-α plays a crucial role in the remodeling of the growth plate, where inactivation of EGFR results in the inability of hypertrophic chondrocytes to degrade the surrounding collagen matrix and to attract osteoclasts to invade and remodel the advancing growth plate under control of the osteoclast differentiation factor receptor activator of nuclear factor κB (NFκB) ligand (RANKL).[75,76] Mice lacking ADAM17 in chondrocytes *(Adam17ΔCh)* show an expanded hypertrophic zone in the growth plate,[77] essentially phenocopying mice with defects in EGFR signaling in chondrocytes.[75] Tight regulation of EGFR signaling is important for cartilage and joint homeostasis, as shown in mice with cartilage-specific deletion of the mitogen-inducible gene 6 (MIG-6), a scaffold protein that binds EGFR and targets it for internalization and degradation.[78] These events of cartilage matrix remodeling and vascular invasion are required for the migration and differentiation of osteoclasts and osteoblasts, which remove the mineralized cartilage matrix and replace it with bone.

## DEVELOPMENT OF THE JOINT CAPSULE AND SYNOVIUM

The interzone and the contiguous perichondrial envelope, of which the interzone is a part, contain the mesenchymal cell precursors that give rise to other joint components, including the joint capsule, synovial lining, menisci, intracapsular ligaments, and tendons.[7-9] The external mesenchymal tissue condenses as a fibrous capsule. The peripheral mesenchyme becomes vascularized and is incorporated as the synovial mesenchyme, which differentiates into a pseudomembrane at about the same time as cavitation begins in the central interzone (stage 23, approximately 8 weeks). The menisci arise from the eccentric portions of the articular interzone. In common usage, the term *synovium* refers to the true synovial lining and the subjacent vascular and areolar tissue, up to—but excluding—the capsule. Synovial lining cells can be distinguished as soon as the multiple cavities within the interzone begin to coalesce. At first, these cells are exclusively fibroblast-like (type B) cells.

As the joint cavity increases in size, synovial-lining cell layers expand by proliferation of fibroblast-like cells and recruitment of macrophage-like (type A) cells from the circulation. The synovial lining cells express the hyaluronan receptor CD44 and UDPGD, the levels of which remain elevated after cavitation. This increased activity likely contributes to the high concentration of hyaluronan in joint fluids. Further synovial expansion results in the appearance of synovial villi at the end of the second month, early in the fetal period, which greatly increases the surface area available for exchange between the joint cavity and the vascular space. Cadherin 11 is an additional molecule expressed by synovial lining cells.[79,80] It is essential for establishment of synovial lining architecture during development, where its expression correlates with cell migration and tissue outgrowth of the synovial lining.

The role of innervation in the developing joint is not well understood. A dense capillary network develops in the subsynovial tissue, with numerous capillary loops that penetrate into the true synovial lining layer. The human synovial microvasculature is already innervated by 8 weeks (stage 23) of gestation, around the time of joint cavitation. Evidence of neurotransmitter function is not found until much later, however, with the appearance of the sensory neuropeptide substance P at 11 weeks. The putative sympathetic neurotransmitter, neuropeptide Y, appears at 13 weeks of gestation, along with the catecholamine-synthesizing enzyme tyrosine hydroxylase. The finding that the *Slit2* gene, which functions for the guidance of neuronal axons and neurons, is expressed in the mesenchyme and in peripheral mesenchyme of the limb bud (stages 23 to 28) suggests that innervation is an integral part of synovial joint development.[81]

## DEVELOPMENT OF NONARTICULAR JOINTS

In contrast to articular joints, the temporomandibular joint develops slowly, with cavitation at a crown-rump length of 57 to 75 mm (i.e., well into the fetal stage). This slow development may occur because this joint develops in the absence of a continuous blastema and involves the insertion between bone ends of a fibrocartilaginous disk that arises from muscular and mesenchymal derivatives of the first pharyngeal arch. However, many of the same genes as those involved in articular joint development are involved in morphogenesis and growth of the temporomandibular joint.[82]

The development of other types of joints, such as synarthroses, is similar to that of diarthrodial joints except that cavitation does not occur, and synovial mesenchyme is not formed. In these respects, synarthroses and amphiarthroses resemble the "fused" peripheral joints induced by paralyzing chicken embryos, and they may develop as they do because relatively little motion is present during their formation.[83]

The intervertebral disk consists of a semiliquid nucleus pulposus (NP) in the center, surrounded by a multilayered fibrocartilaginous annulus fibrosus (AF), which is sandwiched between the cartilaginous end plates (EPs).[84] Between the EPs lies the vertebral body consisting of the growth plate, which later disappears, and the primary and secondary centers of ossification that fuse together. The cells in the NP arise from the embryonic notochord and the notochord orchestrates somatogenesis, from which arises the ventral mesenchymal sclerotome that forms the AF of the intervertebral disk, as well as the vertebral bodies and ribs.[84] The NP acts as the center for controlling cell differentiation in the AF and EP through Shh signaling, which is regulated by WNT signaling and, in turn, promotes growth and differentiation through downstream transcription factors, Brachyury and Sox9, and gene expression of extra-cellular matrix components.[85,86] The proteoglycans and collagens expressed during development of the intervertebral disk have been mapped and reflect the complex structure-function relationships that allow flexibility and resistance to compression in the spine.[87]

## DEVELOPMENT OF ARTICULAR CARTILAGE

In the vertebrate skeleton, cartilage is the product of cells from three distinct embryonic lineages. Craniofacial cartilage is formed from cranial neural crest cells; the cartilage of the axial skeleton (intervertebral disks, ribs, and sternum)

forms from paraxial mesoderm (somites); and the articular cartilage of the limbs is derived from the lateral plate mesoderm.[1] In the developing limb bud, mesenchymal condensations, followed by chondrocyte differentiation and maturation, occur in digital zones, whereas undifferentiated mesenchymal cells in the interdigital web zones undergo cell death. Embryonic cartilage is destined for one of several fates: It can remain as permanent cartilage, as on the articular surfaces of bones, or it can provide a template for the formation of bones by endochondral ossification. During development, chondrocyte maturation expands from the central site of the original condensation, which forms the cartilage anlage resembling the shape of the future bone, toward the ends of the forming bones. During joint cavitation, the peripheral interzone is absorbed into each adjacent cartilaginous zone, evolving into the articular surface. The articular surface is destined to become a specialized cartilaginous structure that does not normally undergo vascularization and ossification.[4,8,9]

More recent evidence indicates that postnatal maturation of the articular cartilage involves an appositional growth mechanism originating from progenitor cells at the articular surface, rather than an interstitial mechanism. During formation of the mature articular cartilage, the differentiated articular chondrocytes synthesize the cartilage-specific matrix molecules, such as type II collagen and aggrecan (see Chapter 3). Through the processes described previously, the articular joint spaces are developed and lined on all surfaces either by cartilage or by synovial lining cells. These two different tissues merge at the enthesis, the region at the periphery of the joint where the cartilage melds into bone, and where ligaments and the capsule are attached. In the postnatal growth plate, the differentiation of the perichondrium also is linked to the differentiation of the chondrocytes in the epiphysis to form the different zones of the growth plate, contributing to longitudinal bone growth. Once the growth plate closes in the human joint, the adult articular cartilage must be maintained by the resident chondrocytes with low-turnover production of matrix proteins.[88,89]

## ORGANIZATION AND PHYSIOLOGY OF THE MATURE JOINT

The unique structural properties and biochemical components of diarthrodial joints make them extraordinarily durable load-bearing devices. The mature diarthrodial joint is a complex structure, influenced by its environment and mechanical demands (see Chapter 6). Joints have structural differences that are determined by their different functions. The shoulder joint, which demands an enormous range of motion, is stabilized primarily by muscles, whereas the hip, which requires motion and antigravity stability, has an intrinsically stable ball-and-socket configuration. The components of the "typical" synovial joint are the synovium, muscles, tendons, ligaments, bursae, menisci, articular cartilage, and subchondral bone. The anatomy and physiology of muscles are described in detail in Chapter 5.

## SYNOVIUM

The synovium, which lines the joint cavity, is the site of production of synovial fluid that provides the nutrition for the articular cartilage and lubricates the cartilage surfaces. The synovium is a thin membrane between the fibrous joint capsule and the fluid-filled synovial cavity that attaches to skeletal tissues at the bone-cartilage interface and does not encroach on the surface of the articular cartilage. It is divided into functional compartments: the lining region (synovial intima), the subintimal stroma, and the neurovasculature (Figure 1-5). The synovial intima, also termed *synovial lining*, is the superficial layer of the normal synovium that is in contact with the intra-articular cavity. The synovial lining is loosely attached to the subintima, which contains blood vessels, lymphatics, and nerves. Capillaries and arterioles generally are located directly underneath the synovial intima, whereas venules are located closer to the joint capsule.

A transition from loose to dense connective tissue occurs from the joint cavity to the capsule. Most cells in the normal subintimal stroma are fibroblasts and macrophages, although

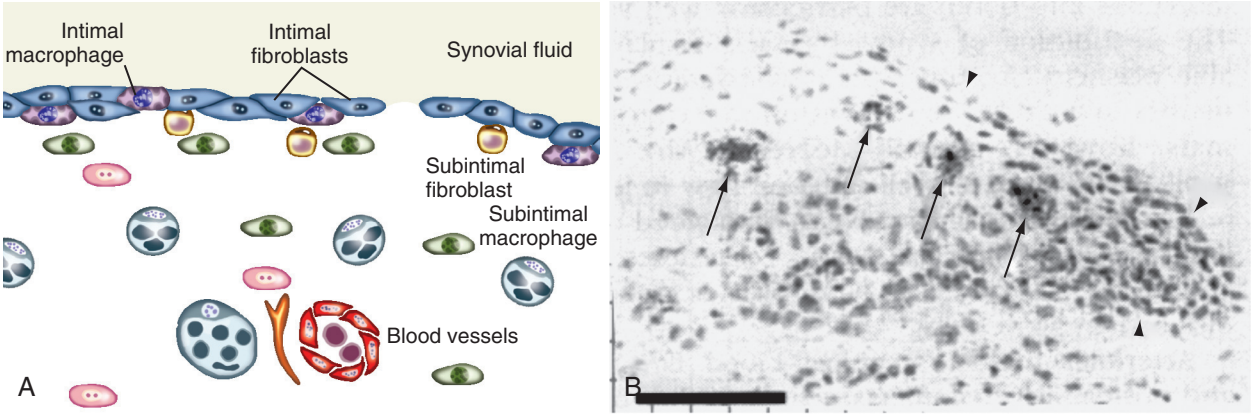

**Figure 1-5** **A,** Schematic representation of normal human synovium. The intima contains specialized fibroblasts expressing vascular cell adhesion molecule-1 (VCAM-1) and uridine diphosphoglucose (UDPG) and specialized macrophages expressing FcγRIIIa. The deeper subintima contains unspecialized counterparts. **B,** Microvascular endothelium in human synovium contains receptors for the vasodilator/growth factor substance P. Silver grains represent specific binding of [$^{125}$I]Bolton Hunter–labeled substance P to synovial microvessels *(arrows)*. *Arrowheads* indicate the synovial surface. Calibration bar = 1 μm. ***(A,** from Edwards JCW: Fibroblast biology: development and differentiation of synovial fibroblasts in arthritis.* Arthritis Res *2:344–347, 2000.)*

adipocytes and occasional mast cells are present.[90] These compartments are not circumscribed by basement membranes but nonetheless have distinct functions; they are separated from each other by chemical barriers, such as membrane peptidases, which limit the diffusion of regulatory factors between compartments. Synovial compartments are unevenly distributed within a single joint. Vascularity is high at the enthesis where synovium, ligament, and cartilage coalesce. Far from being a homogeneous tissue in continuity with the synovial cavity, synovium is highly heterogeneous, and synovial fluid may be poorly representative of the tissue-fluid composition of any synovial tissue compartment. In rheumatoid arthritis, the synovial lining of diarthrodial joints is the site of the initial inflammatory process. This lesion is characterized by proliferation of the synovial lining cells, increased vascularization, and infiltration of the tissue by inflammatory cells, including B and T lymphocytes, plasma cells, and activated macrophages (see Chapter 69).[91-94] The roles of synovitis and synovial angiogenesis are also of current interest in relation to the progression and severity of joint damage in osteoarthritis (OA).[95,96]

## Synovial Lining

The synovial lining, a specialized condensation of mesenchymal cells and extra-cellular matrix, is located between the synovial cavity and stroma. In normal synovium, the lining layer is two to three cells deep, although intra-articular fat pads usually are covered by only a single layer of synovial cells, and ligaments and tendons are covered by synovial cells that are widely separated. At some sites, lining cells are absent, and the extra-cellular connective tissue constitutes the lining layer. Such "bare areas" become increasingly frequent with advancing age. Although the synovial lining is often referred to as the synovial membrane, the term *membrane* is more correctly reserved for endothelial and epithelial tissues that have basement membranes, tight intercellular junctions, and desmosomes. Instead, synovial lining cells lie loosely in a bed of hyaluronate interspersed with collagen fibrils; this is the macromolecular sieve that imparts the semipermeable nature of the synovium. The absence of any true basement membrane is a major determinant of joint physiology.

Early electron microscopic studies characterized lining cells as macrophage-derived type A and fibroblast-derived type B cells. High UDPGD activity and CD55 are used to distinguish type B synovial cells, whereas nonspecific esterase and CD68 typify type A cells. Normal synovium is lined predominantly by fibroblast-like synoviocytes, whereas macrophage-like synovial cells compose only 10% to 20% of lining cells (see Figure 1-5).[92]

Type A, macrophage-like synovial cells contain vacuoles, a prominent Golgi apparatus, and filopodia, but they have little rough endoplasmic reticulum. These cells express numerous cell surface markers of the monocyte-macrophage lineage, including CD16, CD45, CD11b/CD18, CD68, CD14, CD163, and the immunoglobulin (Ig)G Fc receptor, FcγRIIIa.[90,92] Synovial intimal macrophages are phagocytic and may provide a mechanism by which particulate matter can be cleared from the normal joint cavity. Similar to other tissue macrophages, these cells have little capacity to proliferate and are likely localized to the joint during development. The op/op osteopetrotic mouse that is deficient in macrophages because of an absence of macrophage colony-stimulating factor also lacks synovial macrophages, suggesting that type A synovial cells are of a common lineage with other tissue macrophages. Although they represent only a small percentage of the cells in the normal synovium, the macrophages are recruited from the circulation during synovial inflammation, partly from subchondral bone marrow through vascular channels near the enthesis.

The type B, fibroblast-like synoviocytes contain fewer vacuoles and filopodia than type A cells and have abundant protein-synthetic organelles.[92] Similar to other fibroblasts, lining cells express genes encoding extra-cellular matrix components, including collagens, sulfated proteoglycans, fibronectin, fibrillin-1, and tenascin, and they express intracellular and cell surface molecules such as vimentin and CD90 (Thy-1). They have the potential to proliferate, although proliferation markers are rarely seen in normal synovium. In contrast to stromal fibroblasts, synovial intimal fibroblasts express UDPGD and synthesize hyaluronan, an important constituent of synovial fluid.[90] They also synthesize lubricin, which, together with hyaluronan, is necessary for the low-friction interaction of cartilage surfaces in the diarthrodial joint. Synovial lining cells bear abundant membrane peptidases on their surface that are capable of degrading a wide range of regulatory peptides, such as substance P and angiotensin II.

Normal synovial lining cells also express a rich array of adhesion molecules, including CD44, the principal receptor for hyaluronan; vascular cell adhesion molecule (VCAM)-1; intercellular adhesion molecule (ICAM)-1; and CD55 (decay-accelerating factor).[92] They are essential for cellular attachment to specific matrix components in the synovial lining region, preventing loss into the synovial cavity of cells subjected to deformation and shear stresses during joint movement. Adhesion molecules such as VCAM-1 and ICAM-1 potentially are involved in the recruitment of inflammatory cells during the evolution of arthritis. Cadherins mediate cell-cell adhesion between adjacent cells of the same type. The identification of cadherin-11 as a key adhesion molecule that regulates the formation of the synovial lining during development and the synoviocyte function postnatally has provided the opportunity to examine its role in inflammatory joint disease.[79] Cadherin-11 is highly expressed in fibroblast-like cells at the pannus-cartilage interface in rheumatoid synovium, where it plays a role in the invasive properties of the synovial fibroblasts,[97] and treatment with a cadherin-11 antibody or a cadherin-11 fusion protein reduces synovial inflammation and cartilage erosion in an animal model of arthritis.[80]

## Synovial Vasculature

The subintimal synovium contains blood vessels, providing the blood flow that is required for solute and gas exchange in the synovium itself and for the generation of synovial fluid.[98] The avascular articular cartilage also depends on nutrition in the synovial fluid, derived from the synovial vasculature. The vascularized synovium behaves similar to an endocrine organ, generating factors that regulate synoviocyte function and serving as a selective gateway that recruits cells from the circulation during stress and

inflammation. Finally, synovial blood flow plays an important role in regulating intra-articular temperature.

The synovial vasculature can be divided, on morphologic and functional grounds, into arterioles, capillaries, and venules. In addition, lymphatics accompany arterioles and larger venules.[90] Arterial and venous networks of the joint are complex and are characterized by arteriovenous anastomoses that communicate freely with blood vessels in periosteum and periarticular bone. As large synovial arteries enter the deep layers of the synovium near the capsule, they give off branches, which bifurcate again to form "microvascular units" in the subsynovial layers. The synovial lining region, the surfaces of intra-articular ligaments, and the entheses (in the angle of ligamentous insertions into bone) are particularly well vascularized.[99]

The distribution of synovial vessels, which were formed largely as a result of vasculogenesis during development of the joint, displays considerable plasticity. Vasculogenesis is a dynamic process that depends on the cellular interactions with regulatory factors and the extra-cellular matrix, which are also important in angiogenesis. In inflammatory arthritis, the density of blood vessels decreases relative to the growing synovial mass, creating a hypoxic and acidotic environment.[100,101] Angiogenic factors such as VEGF, acting via VEGF receptors 1 and 2 (Flt1 and Flk2), and basic FGF promote proliferation and migration of endothelial cells, a process that is facilitated by matrix-degrading enzymes and adhesion molecules such as integrin $\alpha v\beta 3$ and E-selectin, expressed by activated endothelial cells. Vessel maturation is facilitated by angiopoietin-1 acting via the Tie-2 receptor. The angiogenic molecules are restricted to the capillary epithelium in normal synovium, but their levels are elevated in inflamed synovium in perivascular sites and areas remote from vessels.[102,103]

### Regulation of Synovial Blood Flow

Synovial blood flow is regulated by intrinsic (autocrine and paracrine) and extrinsic (neural and humoral) systems. Locally generated factors, such as the peptide vasoconstrictors angiotensin II and endothelin-1, act on adjacent arteriolar smooth muscle to regulate regional vascular tone.[99] Normal synovial arterioles are richly innervated by sympathetic nerves containing vasoconstrictors, such as norepinephrine and neuropeptide Y, and by "sensory" nerves that also play an efferent vasodilatory role by releasing neuropeptides, such as substance P and calcitonin gene–related peptide (CGRP). Arterioles regulate regional blood flow. Capillaries and postcapillary venules are sites of fluid and cellular exchange. Correspondingly, regulatory systems are differentially distributed along the vascular axis. Angiotensin-converting enzyme, which generates angiotensin II, is localized predominantly in arteriolar and capillary endothelia and decreases during inflammation. Specific receptors for angiotensin II and for substance P are abundant on synovial capillaries, with lower densities on adjacent arterioles. Dipeptidyl peptidase IV, a peptide-degrading enzyme, is specifically localized to the cell membranes of venular endothelium. The synovial vasculature is not only functionally compartmentalized from the surrounding stroma but also highly specialized along its arteriovenous axis. Other unique characteristics of the normal synovial vasculature include the presence of inducible nitric oxidase synthase–independent 3-nitrotyrosine, a reaction product of peroxynitrite, and the localization of the synoviocyte-derived CXCL12 chemokine on heparan sulfate receptors on endothelial cells, suggesting physiologic roles for these molecules in normal vascular function.

## JOINT INNERVATION

Dissection studies have shown that each joint has a dual nerve supply, consisting of specific articular nerves that penetrate the capsule as independent branches of adjacent peripheral nerves and articular branches that arise from related muscle nerves. The definition of joint position and the detection of joint motion are monitored separately and by a combination of multiple inputs from different receptors in varied systems. Nerve endings in muscle and skin and in the joint capsule mediate sensation of joint position and movement. Normal joints have afferent (sensory) and efferent (motor) innervations consisting of both unmyelinated and sensory thick myelinated A fibers in ligaments, fibrous capsule, menisci and adjacent periosteum, where they are thought to function primarily as sensors for pressure and movements. Sensory A and C fibers terminate as free nerve endings in the fibrous capsule, adipose tissue, ligaments, menisci, and the adjacent periosteum, where they are thought to act as nociceptors and contribute to the regulation of synovial microvascular function.

In normal synovium a dense network of fine unmyelinated nerve fibers follow the courses of blood vessels and extend into the synovial lining layers. These nerve fibers do not have specialized endings and are slow-conducting fibers; they may transmit diffuse, burning, or aching pain sensation. Sympathetic nerve fibers surround blood vessels, particularly in the deeper regions of normal synovium, and contain and release classic neurotransmitters, such as norepinephrine, and neuropeptides that are markers of sensory nerves including substance P, CGRP, neuropeptide Y, and vasoactive intestinal peptide.[98,104]

Afferent nerves containing substance P also have an efferent role in the synovium. Substance P is released from peripheral nerve terminals into the joint, and specific, G protein–coupled receptors for substance P are localized to microvascular endothelium in normal synovium. Abnormalities of articular innervation that are associated with inflammatory arthritis may contribute to the failure of synovial inflammation to resolve. Excessive local neuropeptide release may result in the loss of nerve fibers as a result of neuropeptide depletion. Synovial tissue proliferation without concomitant growth of new nerve fibers may lead to an apparent partial denervation of synovium. Studies in patients suggest that free nerve endings containing substance P may modulate inflammation and the pain pathway in OA. Afferent nerve fibers from the joint play an important role in the reflex inhibition of muscle contraction. Trophic factors generated by motor neurons, such as the neuropeptide CGRP, are important in maintaining muscle bulk and a functional neuromuscular junction. Decreases in motor neuron trophic support during articular inflammation probably contribute to muscle wasting.

Mechanisms of joint pain have been reviewed in detail.[105-107] In a noninflamed joint, most sensory nerve

fibers do not respond to movement within the normal range; these fibers are referred to as silent nociceptors. In an acutely inflamed joint, however, these nerve fibers become sensitized by mediators such as bradykinin, neurokinin 1, and prostaglandins (peripheral sensitization), and as a result, normal movements induce pain. Pain sensation is upregulated or downregulated further in the central nervous system, at the level of the spinal cord and in the brain, by central sensitization and "gating" of nociceptive input. Although the normal joint may respond predictably to painful stimuli, a poor correlation often exists between apparent joint disease and perceived pain in persons with chronic arthritis. Pain associated with joint movements within the normal range is a characteristic symptom described by patients with chronically inflamed joints caused by rheumatoid arthritis. Chronically inflamed joints may not be painful at rest, however, unless they are acutely inflamed.

The expression of substance P and CGRP are upregulated by nerve growth factor (NGF), which belongs to a family of neurotrophins that regulated neuronal growth during embryonic development.[108] Postnatally, NGF and the neurotrophins regulate neuronal regeneration and pain perception. In addition to promoting nerve growth and mediating pain perception, NGF can act together with VEGF to promote blood vessel formation. Angiogenesis and nerve growth thus are linked by common pathways involving NGF, VEGF, and neuropeptides such as CGRP, neuropeptide Y, and semiphorins.[98,109,110]

## TENDONS

Tendons are functional and anatomic bridges between muscle and bone.[111,112] Tendons focus the force of a large mass of muscle into a localized area on bone and, by splitting to form numerous insertions, may distribute the force of a single muscle to different bones. Tendons are formed of longitudinally arranged collagen fibrils embedded in an organized, hydrated proteoglycan matrix with blood vessels, lymphatics, and fibroblasts.[113] Cross-links between adjacent collagen chains or molecules contribute to the tensile strength of the tendon. Tendon collagen fibrillogenesis is initiated during early development by a highly ordered process of alignment involving the actin cytoskeleton and cadherin-11.[114,115] Many tendons, particularly those with a large range of motion, run through vascularized, discontinuous sheaths of collagen lined with mesenchymal cells resembling synovium. Gliding of tendons through their sheaths is enhanced by hyaluronic acid produced by the lining cells. Tendon movement is essential for the embryogenesis and maintenance of tendons and their sheaths.[116,117] Degenerative changes appear in tendons, and fibrous adhesions form between tendons and sheaths when inflammation or surgical incision is followed by long periods of immobilization. At the myotendinous junction, recesses between muscle cell processes are filled with collagen fibrils, which blend into the tendon. At its other end, collagen fibers of the tendon typically blend into fibrocartilage, mineralize, and merge into bone through a fibrocartilaginous transition zone termed the *enthesis*, or insertion site.[118]

Tendon fibroblasts synthesize and secrete collagens, proteoglycans, and other matrix components, such as fibronectin and tenascin C, as well as MMPs and their inhibitors, which can contribute to the breakdown and repair of tendon components.[113] Collagen fibrils in tendon are composed primarily of type I collagen with some type III collagen, but there are regional differences in the distribution of other matrix components. The compressed region contains the small proteoglycans, biglycan, decorin, fibromodulin, and lumican, as well as the large proteoglycan versican. The major components in the tensile region of the tendon are decorin, microfibrillar type VI collagen, fibromodulin, and the proline and arginine-rich end leucine-rich repeat protein (PRELP). The presence of cartilage oligomeric matrix protein, aggrecan, and biglycan and collagen types II, IX, and XI is indicative of fibrocartilage. The collagen fiber orientation at the tendon-to-bone enthesis is important for maintaining microarchitecture by reducing the stress concentrations and shielding the outward splay of the insertion from the highest stresses.[119] Understanding the structure has implications for tendon repair because motion between a tendon graft and bone tunnel may impair early graft incorporation and lead to tunnel widening secondary to bone resorption.[120,121]

Failure of the muscle-tendon apparatus is rare; when it does occur, it is the result of enormous, quickly generated forces across a joint and usually occurs near the tendon insertion into bone.[122] Factors that may predispose to tendon failure are aging processes, including loss of extra-cellular water and the increase in intermolecular cross-links of collagen; tendon ischemia; iatrogenic factors, including injection of glucocorticoids; and deposition of calcium hydroxyapatite crystals within the collagen bundles. Alterations in collagen fibril composition and structure are associated with tendon degeneration during aging and may predispose to OA. Understanding the contributions in tendon development of Sox9, scleraxis, Mohawk, members of the TGF-β/BMP superfamily, including GDF-5, and Wnt/β-catenin, and Ihh signaling[123,124] may point to strategies for tendon repair.[122,125]

## LIGAMENTS

Ligaments, which provide a stabilizing bridge between bones, permit a limited range of movement.[126] Ligaments often are recognized only as hypertrophied components of the fibrous joint capsule and are structurally similar to tendons.[127] Although the fibers are oriented parallel to the longitudinal axis of both tissues, the collagen fibrils in ligaments are nonparallel and arranged in fibers that are oriented roughly along the long axis in a wavy, undulating pattern, or "crimp," which can straighten in response to load. Some ligaments have a higher ratio of elastin to collagen (1 : 4) than do tendons (1 : 50), which permits a greater degree of stretch. Ligaments also have larger amounts of reducible cross-links, more type III collagen, slightly less total collagen, and more glycosaminoglycans compared with tendons. The cells in ligaments seem to be more metabolically active than the cells in tendons and have more plump cellular nuclei and higher DNA content.

During postnatal growth, the development of ligament attachment zones involves changes in the ratios and distribution of types I, III, and V collagen and the synthesis of type II collagen and proteoglycans by fibrochondrocytes

that develop from ligament cells at the attachment zone. Attachment zones are believed to permit gradual transmission of the tensile force between ligament and bone.

Ligaments play a major role in the passive stabilization of joints, aided by the capsule and, when present, menisci. In the knee, the collateral and cruciate ligaments provide stability when there is little or no load on the joint. As compressive load increases, there is an increasing contribution to stability from the joint surfaces themselves and the surrounding musculature. Injured ligaments generally heal, and structural integrity is restored by contracture of the healing ligament so it can act again as a stabilizer of the joint.

## BURSAE

The many bursae in the human body facilitate gliding of one tissue over another, much as a tendon sheath facilitates movement of its tendon. Bursae are closed sacs, lined sparsely with mesenchymal cells that are similar to synovial cells, but they are generally less well vascularized than synovium. Most bursae differentiate concurrently with synovial joints during embryogenesis. Throughout life, trauma or inflammation may lead to the development of new bursae, hypertrophy of previously existing ones, or communication between deep bursae and joints. In patients with rheumatoid arthritis, communications may exist between the subacromial bursae and the glenohumeral joint, between the gastrocnemius or semimembranosus bursae and the knee joint, and between the iliopsoas bursa and the hip joint. It is unusual, however, for subcutaneous bursae, such as the prepatellar bursa or olecranon bursa, to develop communication with the underlying joint.[128]

## MENISCI

The meniscus, a fibrocartilaginous, wedge-shaped structure, is best developed in the knee but also is found in the acromioclavicular and sternoclavicular joints, the ulnocarpal joint, and the temporomandibular joint. Until more recently, menisci were thought to have little function and a quiescent metabolism with no capability of repair, although early observations indicated that removal of menisci from the knee could lead to premature arthritic changes in the joint. Evidence from arthroscopic studies of patients with anterior cruciate ligament insufficiency indicates that disease of the medial meniscus correlates with that of the medial femoral cartilage. The meniscus is now considered to be an integral component of the knee joint that has important functions in joint stability, load distribution, shock absorption, and lubrication.[129,130]

The microanatomy of the meniscus is complex and age dependent.[131] The characteristic shapes of the lateral and the medial menisci are achieved early in prenatal development. At that time, the menisci are cellular and highly vascularized; with maturation, vascularity decreases progressively from the central margin to the peripheral margin. After skeletal maturity, the peripheral 10% to 30% of the meniscus remains highly vascularized by a circumferential capillary plexus and is well innervated. Tears in this vascularized peripheral zone may undergo repair and remodeling. The central portion of the mature meniscus is an avascular fibrocartilage, however, without nerves or lymphatics, consisting of cells surrounded by an abundant extra-cellular matrix of collagens, chondroitin sulfate, dermatan sulfate, and hyaluronic acid. Tears in this central zone heal poorly, if at all.

Collagen constitutes 60% to 70% of the dry weight of the meniscus and is mostly type I collagen, with lesser amounts of types III, V, and VI. A small quantity of cartilage-specific type II collagen is localized to the inner, avascular portion of the meniscus. Collagen fibers in the periphery are mostly circumferentially oriented, with radial fibers extending toward the central portion. Elastin content is around 0.6%, and proteoglycan content is around 2% to 3% dry weight. Aggrecan and decorin are the major proteoglycans in the adult meniscus. Decorin is the predominant proteoglycan synthesized in the meniscus from young persons, whereas the relative proportion of aggrecan synthesis increases with age. Although the capacity of the meniscus to synthesize sulfated proteoglycans decreases after the teenage years, the age-related increases in expression of decorin and aggrecan mRNA suggest that the resident cells are able to respond quickly to alterations in the biomechanical environment.

The meniscus was defined originally as a fibrocartilage, based on the rounded or oval shape of most of the cells and the fibrous microscopic appearance of the extra-cellular matrix. Based on molecular and spatial criteria, three distinct populations of cells are recognized in the meniscus of the knee joint[132]:

1. The fibrochondrocyte is the most abundant cell in the middle and inner meniscus, synthesizing primarily type I collagen and relatively small amounts of type II and III collagens. It is round or oval in shape and has a pericellular filamentous matrix containing type VI collagen.
2. The fibroblast-like cells lack a pericellular matrix and are located in the outer portion of the meniscus. They are distinguished by long, thin, branching cytoplasmic projections that stain for vimentin. They make contact with other cells in different regions via connexin 43–containing gap junctions. The presence of two centrosomes, one associated with a primary cilium, suggests a sensory, rather than motile, function that could enable the cells to respond to circumferential tensile loads rather than compressive loads.
3. The superficial zone cells have a characteristic fusiform shape with no cytoplasmic projections. The occasional staining of these cells in the uninjured meniscus with α-actin and their migration into surrounding wound sites suggest that they are specialized progenitor cells that may participate in a remodeling response in the meniscus and surrounding tissues.

Cell lineage tracing and gene profiling studies in mouse embryos have provided insight into the complexity of the meniscus and how it was formed.[133,134] Researchers have considerable interest in using this information to develop new strategies for meniscal generation.

## MATURE ARTICULAR CARTILAGE

Articular cartilage is a specialized connective tissue that covers the weight-bearing surfaces of diarthrodial joints.

The principal functions of cartilage layers covering bone ends are to permit low-friction, high-velocity movement between bones, to absorb the transmitted forces associated with locomotion, and to contribute to joint stability. Lubrication by synovial fluid provides frictionless movement of the articulating cartilage surfaces. Chondrocytes (see Chapter 3) are the single cellular component of adult hyaline articular cartilage and are responsible for synthesizing and maintaining the highly specialized cartilage matrix macromolecules. The cartilage extra-cellular matrix is composed of an extensive network of collagen fibrils, which confers tensile strength, and an interlocking mesh of proteoglycans, which provides compressive stiffness through the ability to absorb and extrude water. Numerous other noncollagenous proteins also contribute to the unique properties of cartilage (Table 1-1). Histologically, the tissue appears to be fairly homogeneous and clearly distinguished from the calcified cartilage and underlying subchondral bone (Figure 1-6). However, this appearance is misleading because significant topographical and regional differences exist in the molecular organization and composition of the articular cartilage, as described in Chapter 3.

*The collagens, proteoglycans, and other noncollagenous proteins in the cartilage matrix are synthesized by chondrocytes at different stages during development and growth of cartilage. In mature articular cartilage, proteoglycans and other noncollagen proteins are turned over slowly, whereas the collagen network is stable unless exposed to proteolytic cleavage. Proteins that are associated with chondrocyte cell membranes also are listed because they permit specific interactions with extra-cellular matrix proteins. The specific structure-function relationships are discussed in Chapter 3 and described in Table 3-1.

DS-PG, Dermatan sulfate proteoglycan; SCGP, small cartilage–derived glycoprotein; SZP, superficial zone protein; YKL-40, 40KD chitinase 3-like glycoprotein.

## SUBCHONDRAL BONE

Subchondral bone is not a homogeneous tissue and consists of a layer of compact cortical bone and an underlying system of cancellous bone organized into a trabecular network.[135,136] The subchondral bone is separated from the overlying articular cartilage by a thin zone of calcified cartilage. The so-called tidemark defines the transition zone between the articular and calcified cartilage. This complex biocomposite of bone and calcified cartilage provides an optimal system for distributing loads that are transmitted from the weight-bearing surfaces that are lined by the hyaline articular cartilage. Although the tidemark was originally believed to form a barrier to fluid flow, evidence shows that biologically active molecules can transit this zone, providing a mechanism by which products produced by chondrocytes or bone cells can influence the activity of the other cell type.[137,138] In addition, further communication is provided via products released from vascular elements in channels that penetrate the calcified cartilage from the adjacent marrow space.[139] Under physiologic conditions the composition and structural organization of the subchondral bone and calcified cartilage are optimally adapted to transfer loads, but several conditions can lead to changes in the structural and functional properties of these tissues.

The subchondral bone undergoes continuous structural reorganization throughout postnatal life. These alterations are mediated by the coordinated activity of bone-resorbing osteoclasts and bone-forming osteoblasts that remodel and adapt the bone in response to local biomechanical and biological signals.[140] Several lines of evidence have established that osteocytes are the bone cell type that plays a key role in regulating the bone remodeling process.[141,142] Osteocytes are distributed throughout the mineralized bone matrix, forming an interconnected network that is ideally positioned to sense and respond to local and systemic stimuli. These effects are mediated via both cell-cell interactions with osteoclasts and osteoblasts but also via signaling through the release of soluble mediators. These products include RANKL, the essential regulator of osteoclast differentiation and activity and its inhibitor osteoprotegerin (OPG),[143,144] as well as additional mediators, including prostanoids, nitric oxide, nucleotides, and a broad spectrum of growth factors and cytokines.[145] In addition to these factors, osteocytes also produce sclerostin and Dickkopf-related protein 1 (DKK-1), which are potent inhibitors of the Wnt/β-catenin pathway that contributes to the regulation of osteoblast-mediated bone formation.[146] The release of RANKL and OPG and the Wnt pathway regulators, DKK-1 and sclerostin, play a major role in controlling the

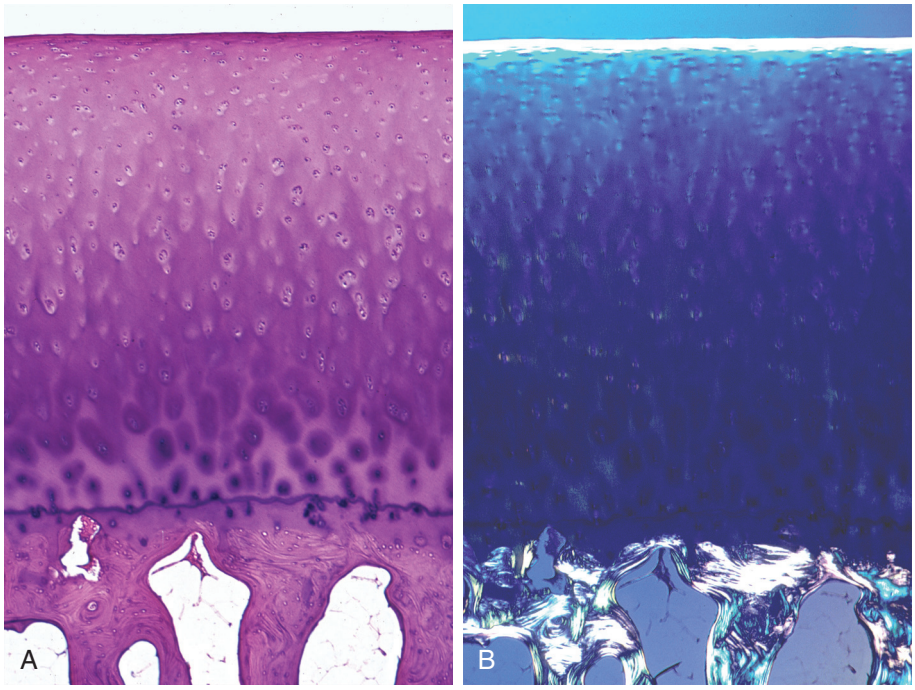

**Figure 1-6** Representative sections of normal human adult articular cartilage, showing nearly the same field in plain **(A)** and polarized **(B)** light. Note the clear demarcation of the articular cartilage from the calcified cartilage below the tidemark and the underlying subchondral bone. adaptation of the subchondral bone to alterations in mechanical loading in both physiologic and pathologic conditions.

The maintenance of the structural and functional integrity of articular cartilage and subchondral bone under physiologic loading is evidence of the unique and intimate interaction of these tissues, but controversy remains with regard to the relationship between them in the pathogenesis of OA.[147] Radin and Rose[148] proposed that the initiation of early alterations in articular cartilage is caused by an increase in subchondral bone stiffness that adversely affects the function of articular chondrocytes, leading to deterioration in the properties of the articular cartilage and susceptibility to mechanical disruption. Alternatively, it has been proposed that changes in subchondral bone stiffness may be a result of cartilage deterioration.[149-151] The alterations in subchondral bone and cartilage that accompany the osteoarthritic process are not restricted to these tissues but also affect the zone of calcified cartilage, where there is evidence of vascular invasion, advancement of the calcified cartilage, and duplication of the tidemark that contributes to a decrease in articular cartilage thickness.[152,153] The penetration of the vascular channels from the subchondral bone and calcified cartilage into the deep zones of the articular cartilage permit exchange of fluids and soluble mediators between these tissues, providing an additional mechanism by which the subchondral bone and articular cartilage can affect the activity of cells within each of these tissues. These structural alterations in the articular cartilage and periarticular bone may also lead to modification of the contours of the adjacent articulating surfaces, further contributing to the adverse biomechanical environment.[148,154-156]

## SYNOVIAL FLUID AND NUTRITION OF JOINT STRUCTURES

The volume and composition of synovial fluid are determined by the properties of the synovium and its vasculature. Fluid in normal joints is present in small quantities (2.5 mL in the normal knee) sufficient to coat the synovial surface but not sufficient to separate one surface from the other. Tendon sheath fluid and synovial fluid are biochemically similar. Both are essential for the nutrition and lubrication of adjacent avascular structures, including tendons and articular cartilage, and for limiting adhesion formation and maintaining movement. Characterization and measurement of synovial fluid constituents have proved useful for the identification of locally generated regulatory factors, markers of cartilage turnover, and the metabolic status of the joint, as well as for the assessment of the effects of therapy on cartilage homeostasis. However, interpretation of such data requires an understanding of the generation and clearance of synovial fluid and its various components.

## GENERATION AND CLEARANCE OF SYNOVIAL FLUID

Synovial fluid concentrations of a protein represent the net contributions of synovial blood flow, plasma concentration, microvascular permeability, and lymphatic removal and its production and consumption within the joint space. Synovial fluid is a mixture of a protein-rich ultrafiltrate of plasma and hyaluronan synthesized by synoviocytes.[91] Generation of this ultrafiltrate depends on the differences between intracapillary and intra-articular hydrostatic pressures and

between colloid osmotic pressures of capillary plasma and synovial tissue fluid. Fenestrations (i.e., small pores covered by a thin membrane) in the synovial capillaries and the macromolecular sieve of hyaluronic acid facilitate rapid exchange of small molecules, such as glucose and lactate, assisted—in the case of glucose—by an active transport system. Proteins are present in synovial fluid at concentrations inversely proportional to molecular size, with synovial fluid albumin concentrations being about 45% of those in plasma. Concentrations of electrolytes and small molecules are equivalent to those in plasma.[157]

Synovial fluid is cleared through lymphatics in the synovium, assisted by joint movement. In contrast to ultrafiltration, lymphatic clearance of solutes is independent of molecular size. In addition, constituents of synovial fluid, such as regulatory peptides, may be degraded locally by enzymes, and low-molecular-weight metabolites may diffuse along concentration gradients into plasma. The kinetics of delivery and removal of a protein must be determined (e.g., using albumin as a reference solute) to assess the significance of its concentration in the joint.[158]

Hyaluronic acid is synthesized by fibroblast-like synovial lining cells, and it appears in high concentrations in synovial fluid at around 3 g/L, compared with a plasma concentration of 30 μg/L.[91] Lubricin, a glycoprotein that assists articular lubrication, is another constituent of synovial fluid that is generated by the lining cells.[159] It is now believed that hyaluronan functions in fluid-film lubrication, whereas lubricin is the true boundary lubricant in synovial fluid (see later discussion). Because the volume of synovial fluid is determined by the amount of hyaluronan, water retention seems to be the major function of this large molecule.

Despite the absence of a basement membrane, synovial fluid does not mix freely with extra-cellular synovial tissue fluid.[96] Hyaluronan may trap molecules within the synovial cavity by acting as a filtration screen on the surface of the synovial lining, resisting the movement of synovial fluid out from the joint space. Synovial fluid and its constituent proteins have a rapid turnover time (around 1 hour in normal knees), and equilibrium is not usually reached among all parts of the joint. Tissue fluid around fenestrated endothelium reflects plasma ultrafiltrate most closely, with a low content of hyaluronate compared with synovial fluid. Alternatively, locally generated or released peptides, such as endothelin and substance P, may attain much higher perivascular concentrations than those measured in synovial fluid. However, the turnover time for hyaluronan in the normal joint (13 hours) is an order of magnitude slower than that of small solutes and proteins. Association with hyaluronan may result in trapping of solutes within synovial fluid.

In normal joints, intra-articular pressures are slightly subatmospheric at rest (0 to −5 mm Hg). During exercise, hydrostatic pressure in the normal joint may decrease further. Resting intra-articular pressures in rheumatoid joints are around 20 mm Hg, whereas during isometric exercise, they may increase to greater than 100 mm Hg, well above capillary perfusion pressure and, at times, above arterial pressure. Repeated mechanical stresses can interrupt synovial perfusion during joint movement, particularly in the presence of a synovial effusion.

## SYNOVIAL FLUID AS AN INDICATOR OF JOINT FUNCTION

In the absence of a basement membrane separating synovium or cartilage from synovial fluid, measurements of synovial fluid may reflect the activity of these tissues. A wide range of regulatory factors and products of synoviocyte metabolism and cartilage breakdown may be generated locally within the joint, resulting in marked differences between the composition of synovial fluid and plasma ultrafiltrate. Because little capacity exists for the selective concentration of solutes in synovial fluid, solutes that are present at higher concentrations than in plasma are probably synthesized locally. It is necessary, however, to know the local clearance rate to determine whether the solutes present in synovial fluid at lower concentrations than in plasma are generated locally.[157,158] Because clearance rates from synovial fluid may be slower than those from plasma, synovial fluid levels of drugs or urate may remain elevated after plasma levels have declined.

Plasma proteins are less effectively filtered in inflamed synovium, perhaps because of increased size of endothelial cell fenestrations or because interstitial hyaluronate-protein complexes are fragmented by enzymes associated with the inflammatory process. Concentrations of proteins, such as α2 macroglobulin (the principal proteinase inhibitor of plasma), fibrinogen, and IgM, are elevated in inflammatory synovial fluids (see Figure 1-7), as are associated protein-bound cations. Membrane peptidases may limit the

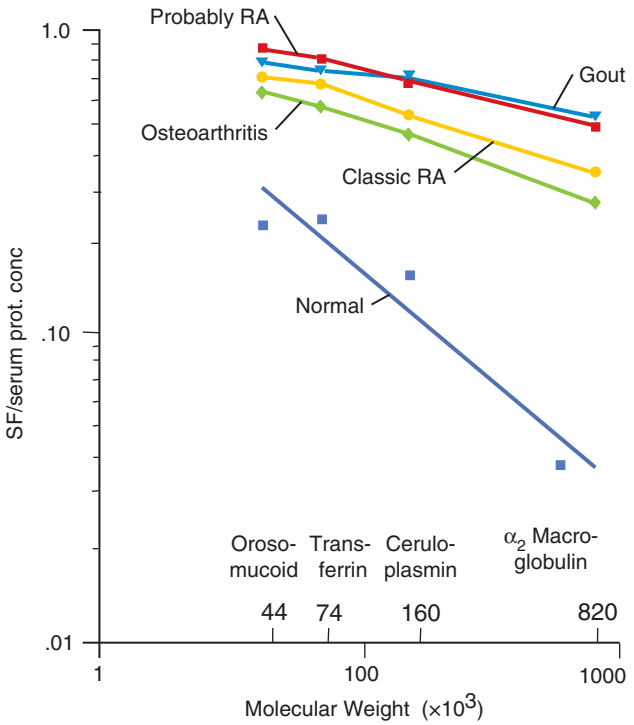

**Figure 1-7** Ratio of the concentration of proteins in synovial fluid to that found in serum, plotted as a function of molecular weight. Larger proteins are selectively excluded from normal synovial fluid, but this macromolecular sieve is less effective in diseased synovium. Prot. conc., Protein concentration; RA, rheumatoid arthritis; SF, synovial fluid. *(From Kushner I, Somerville JA: Permeability of human synovial membrane to plasma proteins.* Arthritis Rheum *14:560, 1971. Reprinted with permission of the American College of Rheumatology.)*

diffusion of regulatory peptides from their sites of release into synovial fluid. In inflammatory arthritis, fibrin deposits may retard flow between the tissue and the liquid phase.

Recently, Sohn and coworkers[160] analyzed synovial fluids and sera from a small series of patients with OA and rheumatoid arthritis using mass spectrometry and multiplex bead-based immunoassays. They identified more than a hundred proteins that were increased in the synovial fluid of patients with OA compared with healthy subjects. Of interest, they found that more than one-third of the proteins in the OA synovial fluid were plasma proteins. They speculated that the presence of these plasma proteins in the synovial fluid could be related to alterations in the endothelial barrier associated with local inflammation in the synovial tissue.

Gobezie and co-workers[161] utilized high-throughput mass spectroscopy-based proteomic analysis to define the protein expression profiles of high abundance synovial fluid proteins in healthy subjects and in patients with early and late OA. They identified 18 proteins that were significantly differentially expressed between the osteoarthritic and control groups. Although all of the differentially expressed proteins were present in the blood and could therefore enter the joint through alterations in vascular permeability associated with the disease state, these molecules were also products of synovial cells and chondrocytes, suggesting that they could be locally produced within the joint. More recently, Ritter et al.[162] utilized a more sensitive method based on gel electrophoresis and mass spectrometry to examine the synovial fluid proteome from patients with OA. They compared the proteomic results with mRNA expression profiles of joint tissues and demonstrated that many of the proteins were derived from synovium or cartilage, providing direct evidence that cells within the joint were a source of the synovial fluid products. Proteins associated with oxidative damage and activation of mitogen-activated protein kinases were among the high-abundance molecules in the OA synovial fluids. They also identified members of the proinflammatory complement cascade in the synovial fluid. Of interest, these molecules have been implicated in the pathophysiology of both OA and rheumatoid arthritis.[163]

## LUBRICATION AND NUTRITION OF THE ARTICULAR CARTILAGE

### Lubrication

Synovial fluid serves as a lubricant for articular cartilage and a source of nutrition for the chondrocytes. Lubrication is essential for protecting cartilage and other joint structures from friction and shear stresses associated with movement under loading. There are two basic categories of joint lubrication. In fluid-film lubrication, cartilage surfaces are separated by an incompressible fluid film, and hyaluronan functions as the lubricant. In boundary lubrication, specialized molecules attached to the cartilage surface permit surface-to-surface contact while decreasing the coefficient of friction. During loading, a noncompressible fluid film is trapped between opposing cartilage surfaces and prevents the surfaces from touching. Irregularities in the cartilage surface and its deformation during compression may augment this trapping of fluid. This stable film is approximately 0.1-μm thick in the normal human hip joint, but it can be much thinner in the presence of inflammatory synovial fluids or with increased cartilage porosity.[91]

Lubricin is the major boundary lubricant in the human joint.[159] Lubricin is a glycoprotein, also called superficial zone protein or proteoglycan 4, that is synthesized by synovial cells, chondrocytes, meniscus, and tendon cells.[164,165] It has a molecular weight of 225,000, a length of 200 nm, and a diameter of 1 to 2 nm. Dipalmitoyl phosphatidylcholine, which constitutes 45% of the lipid in normal synovial fluid, acts together with lubricin as a boundary lubricant. In *boundary lubrication*, lubricin functions as a phospholipid carrier via a mechanism that is common to all tissues and protects the cartilage by reducing pathologic deposition of proteins at the cartilage surface.[166] The importance of lubricin in preserving cartilage homeostasis is illustrated by the study of persons with loss-of-function mutations in the lubricin gene, resulting in the camptodactyl-arthopathy-coxa vara-pericarditis syndrome, which is associated with the development of severe premature OA.[167] Of interest, long-term overexpression of lubricin in animal models of OA protects against both age-related and post-traumatic OA through inhibition of transcriptional programs that promote cartilage catabolism and chondrocyte hypertrophy.[168]

### Nutrition

As observed by Hunter in 1743,[169] normal adult articular cartilage contains no blood vessels. Vascularization of cartilage would be expected to alter its mechanical properties. Blood flow would be repeatedly occluded during weight bearing and exercise, with reactive oxygen species generated during reperfusion, resulting in repeated damage to cartilage matrix and chondrocytes. Chondrocytes synthesize specific inhibitors of angiogenesis that maintain articular cartilage as an avascular tissue.[170-173] As a result of the lack of adjacent blood vessels, the chondrocyte normally lives in a hypoxic and acidotic environment, with extra-cellular fluid pH values around 7.1 to 7.2,[174] and it uses anaerobic glycolysis for energy production.[175,176] High lactate levels in normal synovial fluid, compared with paired plasma measurements, partially reflect this anaerobic metabolism.[176] The two sources of nutrients for articular cartilage are the synovial fluid and subchondral blood vessels.

The synovial fluid and, indirectly, the synovial lining, through which synovial fluid is generated, are the major sources of nutrients for articular cartilage. Nutrients may enter cartilage from synovial fluid either by diffusion or by mass transport of fluid during compression-relaxation cycles.[177] Molecules as large as hemoglobin (65 kDa) can diffuse through normal articular cartilage,[178] and the solutes needed for cellular metabolism are much smaller. Diffusion of uncharged small solutes, such as glucose, is not impaired in matrices containing large amounts of glycosaminoglycans, and diffusivity of small molecules through hyaluronate is enhanced.[179,180]

Intermittent compression may serve as a pump mechanism for solute exchange in cartilage. The concept has arisen from observations that joint immobilization or dislocation leads to degenerative changes. In contrast, exercise increases solute penetration into cartilage in experimental systems.[178] During weight bearing, fluid escapes from the

load-bearing region by flow to other cartilage sites. When the load is removed, cartilage re-expands and draws back fluid, exchanging nutrients with waste materials.[181]

In a growing child, the deeper layers of cartilage are vascularized, such that blood vessels penetrate between columns of chondrocytes in the growth plate. It is likely that nutrients diffuse from these tiny end capillaries through the matrix to chondrocytes. Diffusion from subchondral blood vessels is not considered a major route for the nutrition of normal adult articular cartilage because of the barrier provided by its densely calcified lower layer. Nonetheless, partial defects may normally exist in this barrier,[182] and in arthritis, neovascularization of the deeper layers of articular cartilage may contribute to cartilage nutrition and to entry of inflammatory cells and cytokines.[139,152,183]

## CONCLUSION

Normal human synovial joints are complex structures that comprise interacting connective tissue elements that permit constrained and low-friction movement of adjacent bones. The development of synovial joints in the embryo is a highly ordered process involving complex cell-cell and cell-matrix interactions that lead to the formation of the cartilage anlage and interzone and joint cavitation. Understanding of the cellular interactions and molecular factors involved in cartilage morphogenesis and limb development has provided clues to understanding the functions of the synovium, articular cartilage, and associated structures in the mature joint.

The synovial joint is uniquely adapted to respond to environmental and mechanical demands. The synovial lining is composed of two to three cell layers, with no basement membrane separating the lining cells from the underlying connective tissue. The synovium produces synovial fluid, which provides nutrition and lubrication to the avascular articular cartilage. Normal articular cartilage contains a single cell type, the articular chondrocyte, which is responsible for maintaining the integrity of the extracellular cartilage matrix. This matrix consists of a complex network of collagens, proteoglycans, and other noncollagenous proteins, which provide tensile strength and compressive resistance. Proper distribution and relative composition of these proteins is required for the function of cartilage in protecting the subchondral bone from adverse environmental influences.

Maintenance of the unique composition and organization of each joint tissue is crucial for normal joint function, which is compromised in response to inflammation, biomechanical injury, and aging. Knowledge of the normal structure-function relationships within joint tissues is essential for understanding the pathogenesis and consequences of joint diseases.

CHAPTER 2

# Synovium

Douglas J. Veale • Gary S. Firestein

**KEY POINTS**

- **The synovium provides nutrients to cartilage and produces lubricants for the joint.**
- **The intimal lining of the synovium includes macrophage-like and fibroblast-like synoviocytes.**
- **The sublining in normal synovium contains scattered immune cells, fibroblasts, blood vessels, and fat cells.**
- **Fibroblast-like synoviocytes in the intimal lining produce specialized enzymes that synthesize lubricants such as hyaluronic acid.**

## STRUCTURE

The synovium is a membranous structure that extends from the margins of articular cartilage and lines the capsule of diarthrodial joints, including the temporomandibular joint[1] and the facet joints of vertebral bodies (Figure 2-1).[2] The healthy synovium covers intra-articular tendons and ligaments, as well as fat pads, but not articular cartilage or meniscal tissue. Synovium also ensheaths tendons where they pass beneath ligamentous bands and bursas that cover areas of stress such as the patella and the olecranon. The synovial membrane is divided into two general regions: the intima, or synovial lining, and the subintima, otherwise referred to as the *sublining*. The intima represents the interface between the cavity containing synovial fluid and the subintimal layer. No well-formed basement membrane separates the intima from the subintima. In contrast to the pleura or pericardium, it is not a true lining because it lacks tight junctions, epithelial cells, and a well-formed basement membrane. The subintima is composed of fibrovascular connective tissue and merges with the densely collagenous fibrous joint capsule.

### Synovial Lining Cells

The synovial intimal layer is composed of synovial lining cells (SLCs), which are arrayed on the luminal aspect of the joint cavity. SLCs, termed *synoviocytes*, are one to three cells deep, depending on the anatomic location, and extend 20 to 40 μm beneath the lining layer surface. The major and minor axes of SLCs measure 8 to 12 μm and 6 to 8 μm, respectively. The SLCs are not homogeneous and are conventionally divided into two major populations, namely, type A (macrophage-like) synoviocytes and type B (fibroblast-like) synoviocytes.[3]

#### Ultrastructure of Synovial Lining Cells

Transmission electron microscopic analysis shows that the intimal cells form a discontinuous layer, and thus the subintimal matrix can directly contact the synovial fluid (Figure 2-2). The existence of two distinct cell types—type A and type B SLCs—was originally described by Barland and associates,[4] and several lines of evidence, including animal models, detailed ultrastructural studies, and immunohistochemical analyses, indicate that these cells represent macrophages (type A SLCs) and fibroblasts (type B SLCs). Studies of SLC populations in a variety of species, including humans, have found that macrophages make up anywhere from 20% and fibroblast-like cells approximately 80% of the lining cell.[5,6] The existence of the two cell types has been substantiated by similar findings in a wide variety of species, including hamsters, cats, dogs, guinea pigs, rabbits, mice, rats, and horses.[6-14]

Distinguishing different cell populations that form the synovial lining requires immunohistochemistry or transmission light microscopy. At an ultrastructural level, type A cells are characterized by a conspicuous Golgi apparatus, large vacuoles, and small vesicles, and they contain little rough endoplasmic reticulum, giving them a macrophage-like phenotype (Figure 2-3A and B). The plasma membrane of type A cells possesses numerous fine extensions, termed *filopodia*, that are characteristic of macrophages. Type A cells occasionally cluster at the tips of the synovial villi; this uneven distribution explains, at least in part, early reports that suggested that type A cells were the predominant intimal cell type.[4,8] However, the distribution is highly variable and can differ depending on the joint evaluated or even within an individual joint.

Type B SLCs have prominent cytoplasmic extensions that extend onto the surface of the synovial lining (Figure 2-3C and D).[15] Frequent invaginations are seen along the plasma membrane, and a large indented nucleus relative to the area of the surrounding cytoplasm is also a feature. Type B cells have abundant rough endoplasmic reticulum widely distributed in the cytoplasm, and the Golgi apparatus, vacuoles, and vesicles are generally inconspicuous, although some cells have small numbers of prominent vacuoles at their apical aspect. Type B SLCs are known to contain longitudinal bundles of different-sized filaments, supporting their classification as fibroblasts. Desmosomes and gap-like junctions have been described in rat, mouse, and rabbit synovium, but the existence of these structures in human SLCs has never been documented. Although occasional reports describe an intermediate synoviocyte phenotype, it

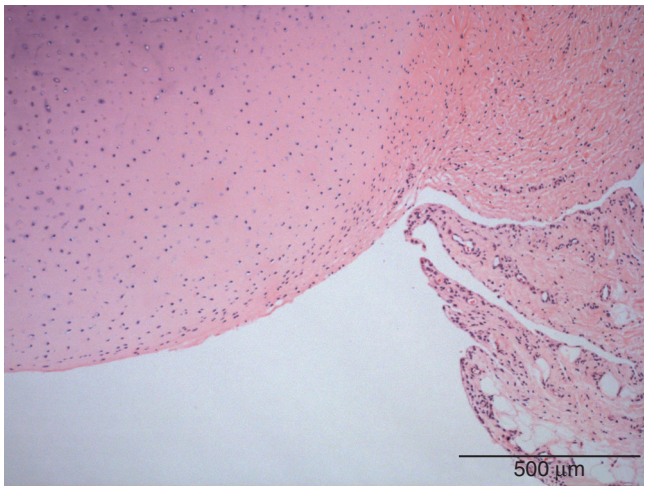

**Figure 2-1** The cartilage-synovium junction. Hyaline articular cartilage occupies the *left half* of this image, and fibrous capsule and synovial membrane occupy the *right half*. A sparse intimal lining layer with a fibrous subintima can be observed extending from the margin of the cartilage across the capsular surface to assume a more cellular intimal structure with areolar subintima.

**Figure 2-2** Transmission electron photomicrograph of synovial intimal lining cells. The cell *on the left* exhibits the dendritic appearance of a synovial intimal fibroblast (type B cell). Other overlying fibroblast dendrites can be observed. Intercellular gaps allow the synovial fluid to be in direct contact with the synovial matrix.

is likely that these cells are functionally conventional type A or B cells.[16,17]

## Immunohistochemical Profile of Synovial Cells

**Synovial Macrophages.** Synovial macrophages and fibroblasts express lineage-specific molecules that can be detected by immunohistochemistry. Synovial macrophages express common hematopoietic antigen CD45 (Figure 2-4A); monocyte/macrophage receptors CD163 and CD97; and lysosomal enzymes CD68 (Figure 2-4B), neuron-specific esterase, and cathepsins B, L, and D. Cells expressing CD14, a molecule that acts as a co-receptor for the detection of bacterial lipopolysaccharide and is expressed by circulating monocytes and monocytes newly recruited to tissue, are rarely seen in the healthy intimal layer, but small numbers are found close to venules in the subintima.[18-24]

The Fcγ receptor, FcγRIII (CD16), which is expressed by Kupffer cells of the liver and type II alveolar macrophages of the lung, is expressed on a subpopulation of synovial macrophages.[25-27] The synovial macrophage population also expresses the class II major histocompatibility complex (MHC) molecule, which plays an important role in the immune response. More recently, the macrophages, which are responsible for the removal of debris, blood, and particulate material from the joint cavity and possess antigen-processing properties, have been found to express Z39Ig, a complement-related protein that is a cell surface receptor and immunoglobulin superfamily member involved in the induction of human leukocyte antigen, DR subregion (HLA-DR) and implicated in phagocytosis and antigen-mediated immune responses.[28-30]

Expression of the β2 integrin chains CD18, CD11a, CD11b, and CD11c varies; CD11a and CD11c may be absent or weakly expressed on a few lining cells.[31,32] Osteoclasts, which are tartrate resistant and acid phosphatase positive and express the αVβ3 vitronectin and calcitonin receptors, do not appear in the normal synovium.

**Synovial Intimal Fibroblasts.** Synovial intimal and subintimal fibroblasts are indistinguishable by light microscopy. They generally are considered to be closely related in terms of cell lineage, but because of their different microenvironments, they do not always share the same phenotype. They possess prominent synthetic capacity and produce the essential joint lubricants hyaluronic acid (HA) and lubricin.[33] Intimal fibroblasts express uridine diphosphoglucose dehydrogenase (UDPGD), an enzyme involved in HA synthesis that is a relatively specific marker for this cell type. UDPGD converts UDP-glucose to UDP-glucuronate, one of the two substrates required by HA synthase for assembly of the HA polymer.[34] CD44, the nonintegrin receptor for HA, is expressed by all SLCs.[32,35,36]

Synovial fibroblasts also synthesize normal matrix components, including fibronectin, laminin, collagens, proteoglycans, lubricin, and other identified and unidentified proteins. They have the capacity to produce large quantities of metalloproteinases, metalloproteinase inhibitors, prostaglandins, and cytokines. This capacity must provide essential biologic advantages, but the complex physiologic mechanisms relevant to normal function are incompletely delineated. Expression of selected adhesion molecules on synovial fibroblasts probably facilitates the trafficking of some cell populations, such as neutrophils, into the synovial fluid and the retention of others, such as mononuclear leukocytes, in the synovial tissue. Expression of metalloproteinases, cytokines, adhesion molecules, and other cell surface molecules is strikingly increased in inflammatory states.

Specialized intimal fibroblasts express many other molecules that also might be expressed by the intimal macrophage population or by most subintimal fibroblasts, including decay-accelerating factor (CD55), vascular cell adhesion molecule–1,[33,37-40] and cadherin-11.[41,42] PGP.95, a neuronal marker, might be specific for type B synoviocytes in some species.[43] Decay-accelerating factor, which is also expressed on many other cells (most notably erythrocytes), as well as bone marrow cells, interacts with CD97, a glycoprotein that is present on the surface of activated leukocytes, including intimal macrophages, and is thought to be involved in signaling processes early after leukocyte activation.[44,45] In contrast, FcγRIII is expressed by macrophages only when they are in close contact with decay-accelerating factor–positive fibroblasts or decay-accelerating factor–coated fibrillin-1 microfibrils in the extra-cellular matrix.[26]

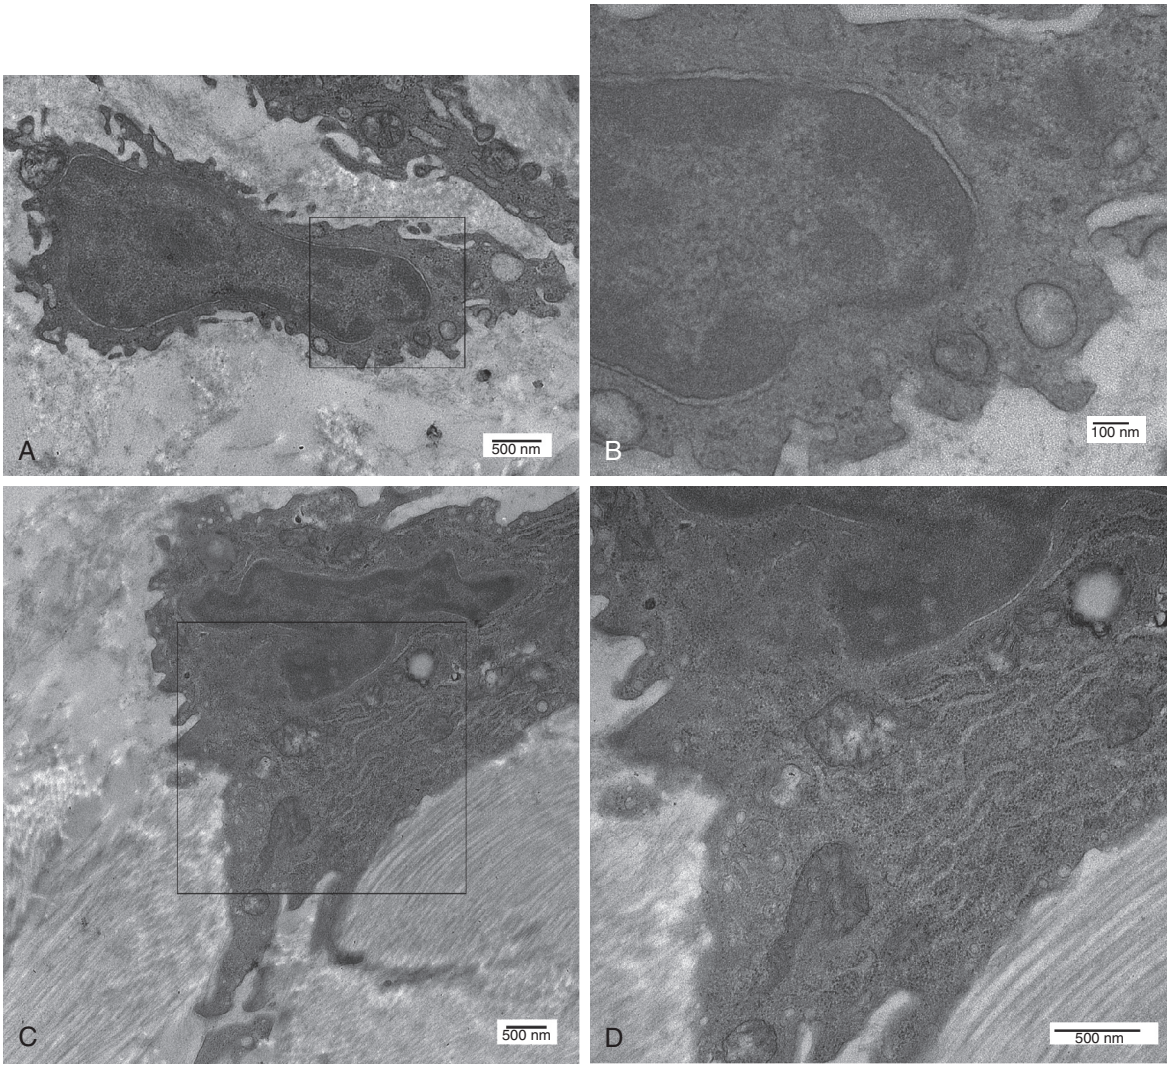

**Figure 2-3** Transmission electron photomicrographs of synovial intimal macrophages (type A cells) and fibroblasts (type B cells). **A,** Low-powered magnification shows the surface fine filopodia, characteristic of macrophages, and a smooth-surfaced nucleus. **B,** The *boxed area* in **A** is shown at a higher magnification, revealing numerous vesicles, characteristic of macrophages. Absence of rough endoplasmic reticulum also is noted. **C,** The convoluted nucleus along with the prominent rough endoplasmic reticulum *(boxed area)* is characteristic of a synovial intimal fibroblast (type B cell). **D,** The rough endoplasmic reticulum is shown at greater magnification.

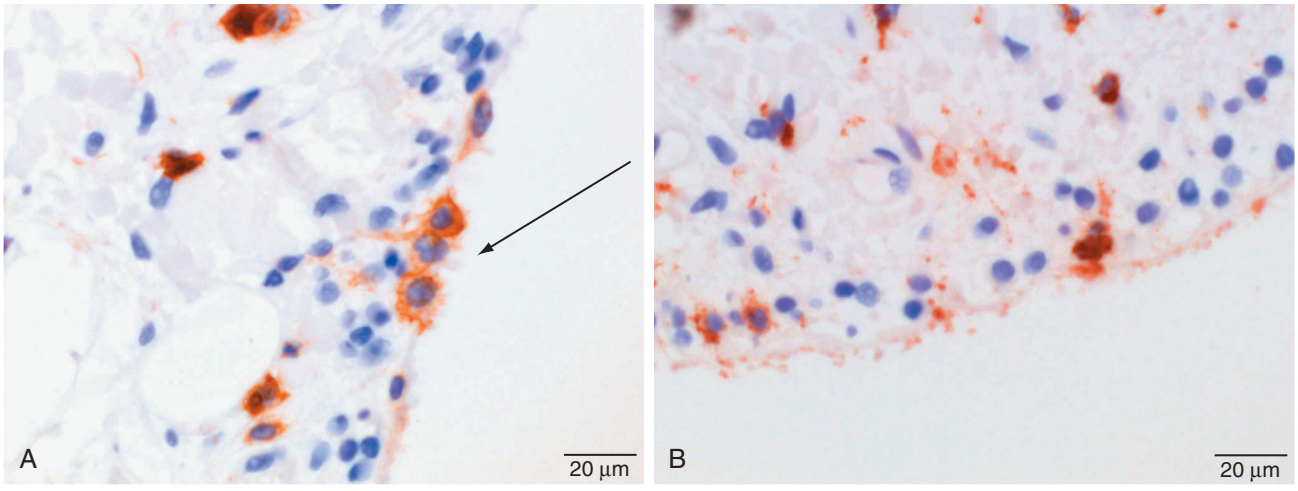

**Figure 2-4** Photomicrographs depicting synovial intimal macrophages by immunohistochemistry. Macrophages are decorated with CD45 (*arrow* in **A**) and CD68 **(B)**, which are markers that identify hematopoietic cells (CD45) and macrophages (CD68).

Toll-like receptors (TLRs) are also expressed on intimal fibroblasts, including TLR2, which is activated by serum amyloid A (among other ligands), leading to angiogenesis and cell invasion that is mediated, at least in part, via the Tie2 signaling pathway.[46,47] Cadherins are a class of tissue-restricted transmembrane proteins that play important roles in homophilic intercellular adhesion and are involved in maintaining the integrity of tissue architecture. Cadherin-11, which was cloned from rheumatoid arthritis (RA) synovial tissue, is expressed in normal synovial intimal fibroblasts but not in intimal macrophages. Fibroblasts transfected with cadherin-11 form a lining-like structure in vitro, which implicates this molecule in the architectural organization of the synovial lining.[41,42,48] This suggestion is supported by the observation that cadherin-deficient mice have a hypoplastic synovial intimal lining and are resistant to inflammatory arthritis.[49] When fibroblasts expressing cadherin-11 are embedded in laminin microparticles, they migrate to the surface and form an intimal lining–like structure.[50] If macrophage lineage cells are included in the culture, they can co-localize with fibroblasts on the surface. Therefore, the organization of the synovial lining, including the distribution of type A and B cells, is orchestrated by fibroblast-like synoviocytes.

β1 and β3 integrins are present on all SLCs, forming receptors for laminin (CD49f and CD49b), types I and IV collagen (CD49b), vitronectin (CD51), CD54 (a member of the immunoglobulin superfamily), and fibronectin (CD49d and CD49e). CD31 (platelet–endothelial cell adhesion molecule), a member of the immunoglobulin superfamily expressed on endothelial cells, platelets, and monocytes, is weakly expressed on SLCs.[32]

## Turnover of Synovial Lining Cells

Proliferation of SLCs in humans is low; when normal human synovial explants have a labeling index of approximately 0.05% to 0.3%[51] when exposed to 3H thimidine.

This labeling index bears a striking contrast to labeling indices of approximately 50% for bowel crypt epithelium. Similar evidence of low proliferation has been found in the synovium of rats and rabbits. The proportion of SLCs expressing the proliferation marker Ki67 is between 1 in 2800 and 1 in 30,000, confirming the relatively slow rate of in situ proliferation.[52] Proliferating cells are generally synovial fibroblasts,[22,53] a finding consistent with the concept that type A synovial cells are terminally differentiated macrophages. Mitotic activity of SLCs is low in inflammatory conditions, such as RA—a condition associated with SLC hyperplasia. Some investigators[54] have reported only rare mitotic figures in RA synovium samples.

Apart from the knowledge that synovial fibroblasts proliferate slowly, little is known about their natural life span, recruitment, or mode of death. Apoptosis is likely involved with maintaining synovial homeostasis, but cultured fibroblast-like synoviocytes tend to be resistant to apoptosis, and very few intimal lining cells display evidence of completed apoptosis by ultrastructural analysis or by labeling for fragmented DNA. The paucity of normal synovium samples for evaluation and the rapid clearance of apoptotic cells could confound the analysis.[55]

## Origin of Synovial Lining Cells

There is little doubt that the type A SLC population is bone marrow–derived and represents cells of the mononuclear phagocyte system.[4] Studies in the Beige (bg) mouse, which harbors a homozygous mutation that confers the presence of giant lysosomes in macrophages, have confirmed the bone marrow origin of these cells.[56,57] Normal mice with bone marrow depleted through irradiation were rescued with bone marrow cells obtained from the bg mouse. Electron microscopic analysis of the synovium from recipient animals revealed that type A SLCs contained the giant lysosomes of the donor bg mouse and that these structures were never identified in type B cells. These findings provide powerful evidence that (1) type A SLCs represent macrophages, (2) they are recruited from the bone marrow, and (3) they are a distinct lineage from type B SLCs.

In addition to immunohistochemistry, several lines of evidence support the concept that type A SLCs are recruited from the bone marrow:

- The osteopetrotic (op/op) mouse, a spontaneously occurring mutant that fails to produce macrophage colony-stimulating factor because of a missense mutation in the *CSF1* gene,[58-60] has low numbers of circulating and resident macrophage colony-stimulating factor–dependent macrophages, including those in the synovium.
- Type A cells in rat synovium do not populate the joint until after the development of synovial blood vessels.[22]
- Type A SLCs are conspicuous around vessels in the synovium in neonatal mice.[6]
- When synovial explants are placed in culture, the reduction in type A SLCs is explained in part by their migration into the culture medium—an observation that reflects the process of migration of macrophages into the synovial fluid in vivo.[1,61]
- Macrophages constitute up to 80% of the cells found around venules in inflammatory conditions such as RA and are cleared rapidly (<48 hours) after successful treatment but will re-accumulate from the circulation if relapse occurs.[62]

Type B intimal cells represent a resident fibroblast population in the synovial lining, but little is known about the cells from which they derive and about how their recruitment is regulated. The existence of mesenchymal stem cells in the synovium suggests that these cells might differentiate into the synovial lining fibroblast. To date, a specific transcription factor directing mesenchymal stem cell differentiation into the synovial fibroblast, similar to factors required for commitment by this multipotential population into bone (cbfa-1), cartilage (Sox-9), and fat (peroxisome proliferator-activated receptor γ [PPARγ]), has not been identified.

Several important signaling pathways are activated in the inflamed synovium, including nuclear factor-κB (NF-κB), Janus kinase/signal transducer and activator of transcription (JAK/STAT), Notch, and hypoxia-inducible factor 1, α subunit (HIF-1α). NF-κB is a key transcriptional regulator in the inflamed synovium.[63] NF-κB signaling is complex and may be activated by cytokines, cell surface

adhesion molecules, and hypoxia.[63,64] NF-κB activation could facilitate synovial hyperplasia by promoting proliferation and inhibiting apoptosis of RA fibroblast-like synoviocytes. One of the key roles of NF-κB is to protect RA fibroblast-like synoviocytes against apoptosis, possibly by countering the cytotoxicity of tumor necrosis factor (TNF) and Fas ligand.[65]

JAK/STAT, Notch, and HIF-1α signaling pathways are also evident in inflamed synovium. STAT3 expression in the synovium correlates with synovitis and is activated by interleukin (IL)-6[66] but also indirectly by TNF. Notch signaling pathway components are predominantly localized to perivascular/vascular regions[67] and are regulated by vascular endothelial growth factor (VEGF) and ang2, which is consistent with the role of mediation of angiogenesis by Notch in inflammation and cancer.[67,68] Interestingly, hypoxia induces activation of phospho (p)-STAT3/p-STAT1, NF-κB, and Notch in synovial cells.[69] Furthermore, Notch/HIF-1α interactions in RA synoviocytes are in part mediated through STAT3 activation,[70] possibly through competition of STAT3 with von Hippel–Lindau tumor suppressor for binding to HIF-1α. Although no direct link between NF-κB and HIF-1α has been demonstrated in the inflamed joint, preferential activation of the canonical NF-κB pathway occurs in RA synovial tissue obtained from patients with more hypoxic joints.[69]

## Subintimal Layer

SLCs are not separated from the underlying subintima by a well-formed basement membrane composed of the typical trilaminar structure seen beneath epithelial mucosa. Nevertheless, most components of basement membrane are present in the extra-cellular matrix surrounding SLCs. These components include tenascin X, perlecan (a heparan sulfate proteoglycan), type IV collagen laminin, and fibrillin-1.[71,72] Of note is the absence of laminin-5 and integrin α3β3γ2, which are components of epithelial hemidesmosomes.[73]

The subintima is composed of loose connective tissue of variable thickness and variable proportions of fibrous/collagenous and adipose tissue, depending on the anatomic site. Under normal healthy conditions, inflammatory cells are virtually absent from the subintima, apart from a sprinkling of macrophages and scattered mast cells.[74] Human synovial tissue is a rich source of mesenchymal stem cells, and although it is unknown which compartment contains this cell population, some cells have the ability to self-renew and differentiate into bone, cartilage, and fat in vitro—a phenomenon that reflects the ability of the cell to regenerate in vivo.[75-77]

Three categories of subintima are well defined: areolar, fibrous, and fatty/adipose types. Under the light microscope, areolar-type subintima, the most commonly studied, generally is found in larger joints in which there is free movement (Figure 2-5A). It is composed of fronds with a cellular intimal lining and loose connective tissue in the subintima, with little in the way of dense collagen fibers, and a rich vasculature. The fibrous subintima is composed of scant, dense, fibrous, poorly vascularized connective tissue, and it has an attenuated layer of SLCs (Figure 2-5B). The adipose type, which contains abundant mature fat cells and has a single layer of SLCs, is seen more commonly with aging and in intra-articular fat pads (Figure 2-5C).

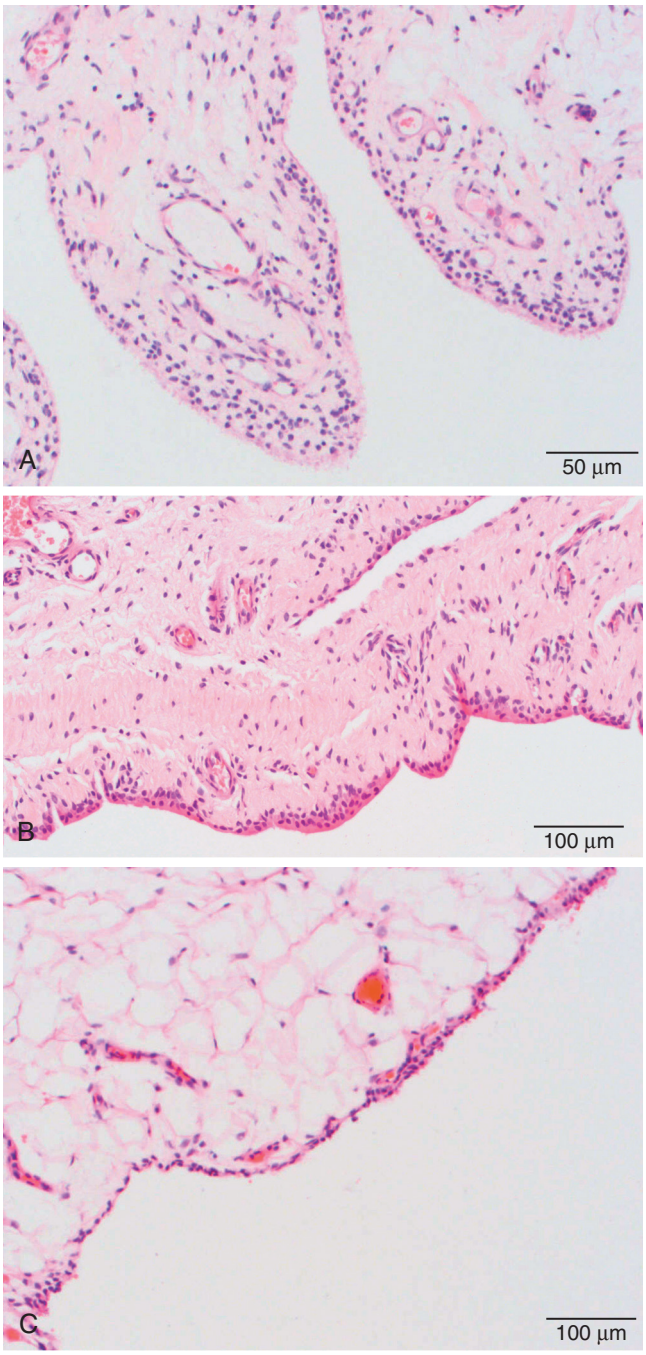

**Figure 2-5** Photomicrographs of different morphologic types of synovial tissue. All photomicrographs show an intimal layer of one to two cells in depth. **A,** The areolar synovium is composed of villous fronds. Beneath the intimal lining layer is cellular loose fibrovascular fatty subintima. **B,** The fibrous synovium comprises dense collagenous material in the subintimal layer. **C,** The subintimal layer of the fatty synovial tissue is composed of less cellular mature adipose tissue with little collagen deposition.

The subintima contains types I, III, V, and VI collagen, glycosaminoglycans, proteoglycans, and extra-cellular matrices, including tenascin and laminins. Integrin receptors for collagens, laminin, and vitronectin are absent or at best weakly expressed by subintimal cells. In contrast,

receptors for fibronectin (CD49d and CD49e) are detected, and CD44, the HA receptor, is strongly expressed in most subintimal cells. β2 integrins are largely limited to perivascular areas, particularly in the subintimal zone, as is CD54.[78]

### Subintimal Vasculature

The vascular supply to the synovium is provided by many small vessels and is shared in part by the joint capsule, epiphyseal bone, and other perisynovial structures. Arteriovenous anastomoses communicate freely with the vascular supply to the periosteum and to periarticular bone. As large synovial arteries enter the deep layers of the synovium near the capsule, they branch to form microvascular units in the more superficial subsynovial layers. Precapillary arterioles probably play a major role in controlling circulation to the lining layer. The surface area of the synovial capillary bed is large, and because it runs only a few cell layers deep to the surface, it has a role in trans-synovial exchange of molecules. The intimal lining, however, is devoid of blood vessels. While few in number, studies have shown that vessels in the normal synovium have an intact pericyte layer, suggesting vessel stability, in contrast to the inflamed joint, where a mix of mature and immature vessels were observed. Neural cell adhesion molecule (NCAM) deficiency and oxidative DNA damage suggest that vessels may remain in a plastic state even after pericyte recruitment.[79,80] After TNF blockade, synovial blood vessels become more stable and resemble normal synovium.

Numerous physical factors influence synovial blood flow. Heat promotes blood flow through synovial capillaries. Exercise enhances synovial blood flow to normal joints but may reduce the clearance rate of small molecules from the joint space. Experiments have shown a substantial vascular reserve capacity in normal articulations. Immobilization reduces synovial blood flow, and pressure on the synovial membrane can act to tamponade the synovial blood supply.

Vascular endothelial lining cells express CD34 and CD31 (Figure 2-6A). They also express receptors for the major components of basement membrane, including laminin and collagen IV, and the integrin receptors CD49a (laminin and collagen receptors), CD49d (fibronectin receptor), CD41, CD51 (vitronectin receptor), and CD61 (the β3 integrin subunit). Endothelial cells express CD44, the HA receptor, and CD62P (P-selectin), which acts as a receptor that supports binding of leukocytes to activated platelets and endothelium. They are only weakly positive in uninflamed synovium, however, for expression of CD54 (intercellular adhesion molecule–1), a receptor for β2 integrins expressed by many leukocytes. The endothelial cells of capillaries in the superficial zone of the subintima are strongly positive for HLA-DR expression by immunohistochemistry, whereas cells in the larger vessels in the deep aspect of the membrane are negative.[32,34]

Hypoxia might be a key driver of endothethlial cell activation and blood vessel formation in the inflamed joint. This theory was originally proposed in 1970,[81] when a synovial fluid electrode was used to demonstrate that a partial pressure of $O_2$ in a knee joint affected by RA was 26.5 mm Hg, which was significantly lower than that in joints affected by osteoarthritis (42.9 mm Hg) or traumatic effusions (63 mm Hg). This observation was supported by studies showing increased glycolytic metabolism in the joint suggestive of increased metabolic activity. Low $pO_2$ in the inflammed synovial membrane was confirmed with $pO_2$ probes, with mean levels approximately 3% compared with normal joints at 7%.[82] The degree of hypoxia in synovium affected by RA and normal synovium was inversely related to the number of blood vessels observed and their level of maturity. In patients responding to TNF blockade, the $pO_2$ increased, thus improving oxygenation to a level similar to that of normal joints.

### Subintimal Lymphatics

Detailed analysis of the number and distribution of lymphatic vessels has been made possible by the use of the antibody to the lymphatic vessel endothelial HA receptor (LYVE-1) (Figure 2-6B).[83] This antibody is highly specific for lymphatic endothelial cells in lymphatic vessels and lymph node sinuses and does not react with endothelial cells of capillaries and other blood vessels that express CD34 and factor VIII–related antigen. Expression of LYVE-1 in lymphatic endothelial cells has been used as a marker to show that lymphatic vessels are less common in the fibrous synovium compared with areolar and adipose variants of human subsynovial tissue. Detection of this molecule reveals that lymphatics are present in the superficial, intermediate, and deeper layers of synovial membrane in synovium from healthy persons or patients with osteoarthritis and joints affected by RA, although the number in the superficial subintimal layer is low in normal synovium. Little difference in the distribution and number is noted between normal and osteoarthritis synovium, which is characterized by lack of villous hypertrophy. Lymphatic channels are plentiful, however, in the subintimal layer in the presence of villous edema hypertrophy and chronic inflammation.

### Subintimal Nerve Supply

The synovium has a rich network of sympathetic and sensory nerves. The former, which are myelinated and detected with the antibody against S-100 protein, terminate close to blood vessels, where they regulate vascular tone (Figure 2-6C through E). Sensory nerves respond to proprioception and pain via large myelinated nerve fibers and via small (<5 μm) unmyelinated or myelinated fibers with unmyelinated free nerve ends (nociceptors). The latter are immunoreactive in the synovium for neuropeptides, including substance P, calcitonin gene–related peptide, and vasoactive intestinal peptides.[84,85]

## FUNCTION

Synthetic and protective functions of individual synovial cell populations are multiple and complex. The composite synovial structure, which includes cell populations and their products, vasculature, nerves, and the intercellular matrix, possesses several specialized functions that are essential for normal joint movement, synovial fluid formation, chondrocyte nutrition, and cartilage protection at multiple

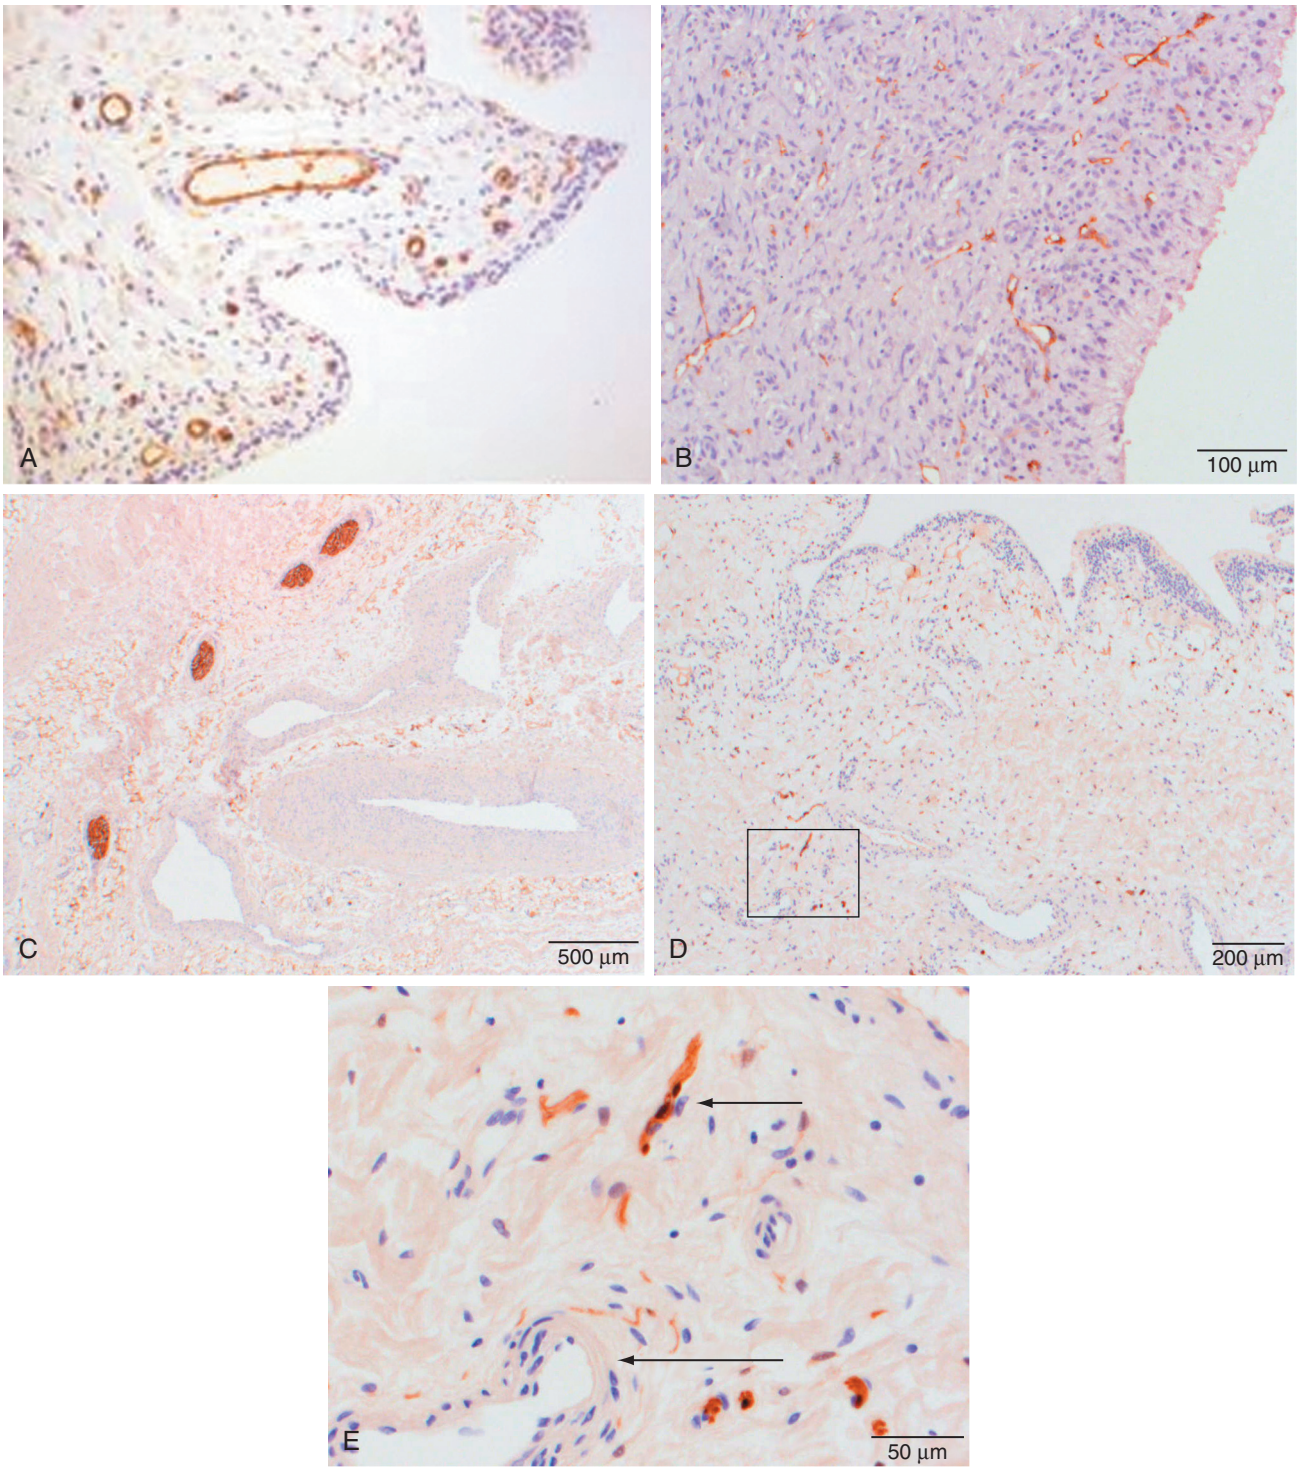

**Figure 2-6** Photomicrographs of synovium show lymphovascular and nervous structures by immunohistochemistry. **A** and **B,** Areolar synovium featuring thin-walled vessels are highlighted with antibody to CD31 **(A),** and lymphatic vessels in an inflamed synovium are highlighted with antibody to lymphatic vessel endothelial HA receptor (LYVE-1) **(B)**. **C,** Deep in the synovial subintima, close to the joint capsule, medium-sized neurovascular bundles are present with nerves highlighted by antibody to S-100. **D,** Within the more superficial synovium, small nerves decorated with S-100 are identified. **E,** The *boxed area* in **D** is shown at a higher magnification. The *upper arrow* is directed at a nerve; the *lower arrow* is directed at a small vessel.

anatomic locations. These functions must be preserved over a lifetime to maintain maximal mobility and independence. Absence of essential constituents of synovial fluid or inadequate cartilage protection results in early articular malfunction, which may progress to local or generalized joint failure.

## Joint Movement

Four characteristics of the synovium are essential for joint movement: deformability, porosity, nonadherence, and lubrication. In a healthy person, the synovium is a highly deformable structure that facilitates movement between

other adjacent, nondeformable structures within the joint. This unique facility of the synovium to enable movement between tissues rather than within tissues has been emphasized[86] and can be attributed to the presence of a free surface that allows synovial tissue to remain separated from adjacent tissues. The ensuing space is maintained by the presence of synovial fluid.

### Deformability

The deformability of normal synovium is considerable because it must accommodate the extreme positional range available to the joint and its adjacent tendons, ligaments, and capsule. When a finger is flexed, the palmar synovium of each interphalangeal joint contracts while the dorsal synovium expands, and as the finger extends, the reverse mechanism occurs. This normal contraction and expansion of synovium seems to involve a folding and unfolding component and an elastic stretching and relaxation of the tissue. During repeated rapid movement, the synovial lining cannot be pinched between cartilage surfaces and for it to successfully retain its integrity and the integrity of synovial blood vessels and lymphatics. Deformability also limits the extent of synovial ischemia-reperfusion injury during joint motion by maintaining a relatively low intra-articular pressure.

### Porosity

The synovial microvasculature and the intimal lining must be porous to permit robust diffusion of nutrients to cartilage. The structure of the intimal lining is ideal for this requirement because of the relatively disorganized basement membrane and lack of tight junctions. Plasma components freely diffuse into the intra-articular space, and most plasma components, including proteins, are present in synovial fluid at about one-third to one-half the plasma concentration.

### Nonadherence

The third important characteristic of the synovium that facilitates joint movement is its nonadherence to opposing surfaces. Intimal cells on the synovial surface adhere to underlying cells and matrix but do not adhere to opposing synovial and cartilage surfaces. The mechanism that preserves this phenomenon of nonadherence is unknown and might involve the arrangement of cell surface and tissue matrix molecules, such as collagen, fibronectin, and HA. Alternatively, nonadherence may result in part from regular movement of the normal synovial lining.

### Lubrication

The fourth characteristic of synovium that is essential for joint motion is an efficient lubrication mechanism to facilitate movement of cartilage on cartilage. The mechanisms of joint lubrication are complex and are an integral component of synovial physiology. In an articulating joint, cartilage is subjected to numerous compressive and frictional forces every day. Friction and wear can never be eliminated from a functioning joint. Adult chondrocytes do not normally divide in vivo, and damaged cartilage has limited capacity for self-repair. For a joint to maintain its function throughout a lifetime of use, protective biologic mechanisms, such as lubrication, help minimize wear and damage that result from normal daily activities. Synovial membrane may also contribute to concentration of lubricants in synovial fluid, because it is a semi-permeable membrane. These functions have recently been replicated by a polytetrafluoroethylene membrane that can be used in a bioreactor system to modulate lubricant retention in bioengineered synovial fluid. Synoviocytes adherent to such membranes may serve as a source of lubricant and a barrier for lubricant transport.[87] Furthermore, cytokines can stimulate normal lubricant production 40- to 80-fold in such bioreactor systems (Figure 2-7).[88]

*Boundary lubrication* refers to the protective effect of particular lubricating molecules adsorbing to a surface and repelling its opposing interface.[89] Bearing surfaces must generate a mutual repulsion to be lubricated in the boundary mode. Boundary lubricants exert their effects by changing the physicochemical characteristics of a surface, and they reduce articular friction and wear by providing a smooth and slippery coating. Friction is reduced by an interposed

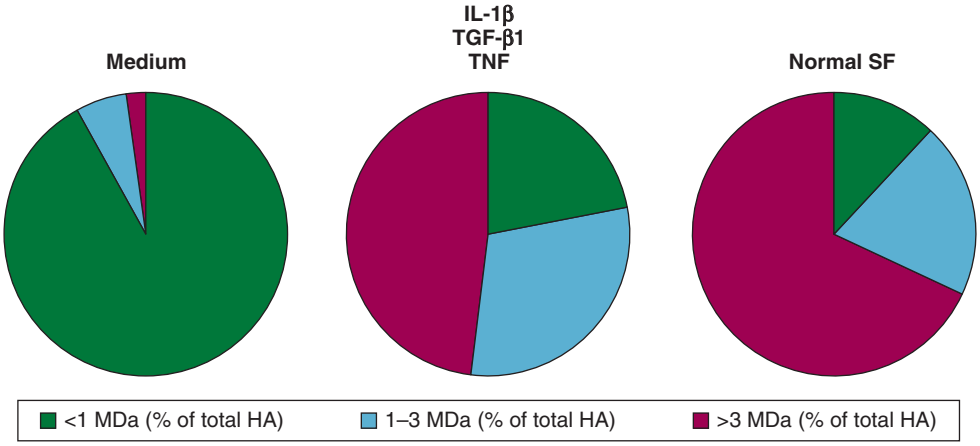

**Figure 2-7** The molecular size of synovial fluid hyaluronic acid (HA) (Normal SF), supernatants of cultured synoviocytes (Medium), and synoviocytes stimulated with IL-1β, TGF-β1 TNF. Note that cells stimulated with the cytokine cocktail closely approximate HA of normal SF compared with control cells, with high molecular weight species that promote a low friction environment. *(Data from Blewis ME, Lao BJ, Schumacher BL, et al: Interactive cytokine regulation of synoviocyte lubricant secretion.* Tissue Eng Part A *16:1329–1337, 2010.)*

film of protective fluid that allows one surface to ride freely over another. The cartilage matrix is integral to this phenomenon because it is fluid filled and compressible. Loaded cartilage extrudes lubricant fluid from its surface, and expressed fluid contributes to the separation of the two articulating surfaces. Scanning electron microscopy has shown a continuous film of fluid, only 100 nm thick, that separates one surface from the other, preventing direct abrasive contact.[90] This ultrathin coating of lubricant resists distraction of the two articulating surfaces, enhancing joint stability. In healthy joints, another essential advantage of an intra-articular lubrication system is the effective prevention of pinching of adjacent, well-vascularized synovial membrane, a feature that is lost in the inflamed joint in which synovial membrane adheres to the cartilage surface.

**Hyaluronic Acid.** HA, a high-molecular-weight polysaccharide, is a major component of synovial fluid and cartilage.[91] It is produced in large amounts by mechanosensitive, fibroblast-like synoviocytes.[92,93] HA, which has three mammalian forms designated HAS1, HAS2, and HAS3,[94] is synthesized by HA synthase at the plasma membrane and is extruded directly into the extra-cellular compartment. HA synthase activity and HA secretion are stimulated by pro-inflammatory cytokines, including IL-1β and TGF-β.[92,95,96] Interestingly, although the levels of cytokines are increased in arthritic joints, the synovial fluid concentration of HA decreases.[97] HA is also synthesized by many other skeletal cells and is an important component of extracellular matrices. It is simultaneously a solid phase matrix element of cartilage and other tissues and a fluid phase element in the synovial space under normal and abnormal conditions.

HA has many biologic functions, which include effects on cell growth, migration, and adhesion. The regulatory role of HA is mediated through HA-binding proteins and receptors, including CD44, which are present on the cell surfaces of chondrocytes, lymphocytes, and other mononuclear cell populations. HA plays a crucial role in morphogenesis and in wound healing. HA also is a vital structural component of the synovial lining, and it has an essential role in the induction of joint cavitation during embryogenesis. HA, which is produced by synovium, was originally thought to be primarily a joint lubricant, and it is generally accepted that it plays a major physiologic role in maintaining synovial fluid viscosity. HA is important in normal joint function, not least through its capacity to provide effective shock absorption. It has been suggested that HA is a particularly important viscohydrodynamic lubricant at low-load interfaces, such as synovium-on-synovium and synovium-on-cartilage.[98] Synovial fluid HA, acting in combination with albumin, has a role in the attenuation of fluid loss from the joint cavity, particularly during periods of increased pressure, which can occur during sustained joint flexion.[99-101]

**Lubricin.** Compelling evidence suggests that lubricin, which was first described in the 1970s,[102] is the factor primarily responsible for boundary lubrication of diarthrodial joints.[103] Lubricin, a large secreted, mucin-like proteoglycan with an apparent molecular weight of 280 kDa, is a product of the gene proteoglycan 4 *(PRG4)*. It is a major component of synovial fluid and is present at the cartilage surface. The gene is highly expressed by human synovial fibroblasts and by superficial zone chondrocytes.[104] Lubricin is closely related to superficial zone protein, megakaryocyte-stimulating factor, and hemangiopoietin, which are encoded by the same gene but can differ in terms of post-translational modification. Superficial zone protein is expressed by SLCs and by superficial zone chondrocytes at the cartilage surface but not by intermediate or deep zone chondrocytes.[105] It has been suggested that lubricin may bind to the much longer hyaluronate polymers, distributing shear stress and stabilizing essential lubricant molecules.[106]

In an experimental model, lubricin seemed to have multiple functions in articulating joints and tendons, including protection of cartilage surfaces from protein deposition and cell adhesion and inhibition of synovial cell overgrowth.[107] *Prg4*$^{-/-}$ mice, which were consistently normal at birth, showed progressive loss of superficial zone chondrocytes and increasing synovial cell hyperplasia (Figure 2-8). The essential role of lubricin in maintaining joint integrity was shown by the identification of disease-causing mutations in patients with the autosomal-recessive disorder camptodactyly–arthropathy–coxa vara–pericarditis (CACP) syndrome.[108] CACP is a large joint arthropathy associated with the absence of lubricin from synovial fluid and ineffective boundary lubrication provided by the synovial fluid (Figure 2-9).[106,109] In other studies of lubricin biology and joint integrity, experimental injury resulted in reduced synovial fluid lubricin concentrations, decreased boundary lubricating ability, and increased cartilage matrix degradation, each of which could be attributed to trauma-induced inflammatory processes.[104]

Other investigators have argued against the primacy of lubricin in joint lubrication by proposing that surface-active phospholipid, which is also secreted by intimal fibroblasts, is the essential boundary lubricant that reduces cartilage friction to remarkably low levels.[110] It was hypothesized that lubricin acts as the carrier of surface-active phospholipid to articular cartilage but is not the lubricant per se, a function that is similar to that of the well-characterized alveolar surfactant binding proteins in the lung.

## Synovial Fluid Formation

In healthy people a constant volume of synovial fluid is important during joint movement as a cushion for synovial tissue and as a reservoir of lubricant for cartilage. Many of the soluble components and proteins in synovial fluid exit the synovial microcirculation through pores or fenestrations in the vascular endothelium, then diffuse through the interstitium before entering the joint space. Synovial fluid is in part a filtrate of plasma to which additional components, including HA and lubricin, are added and removed by the SLCs (Figure 2-10). As noted earlier, concentrations of electrolytes and small molecules in synovial fluid are similar to those in plasma. Synovial permeability to most small molecules is determined by a process of free diffusion through the double barrier of endothelium and interstitium, limited mainly by the intercellular space between SLCs. For most small molecules, synovial permeability is inversely related to the dimensions of the molecule.

Experimental evidence suggests that the exchange of small solutes is determined predominantly by the synovial

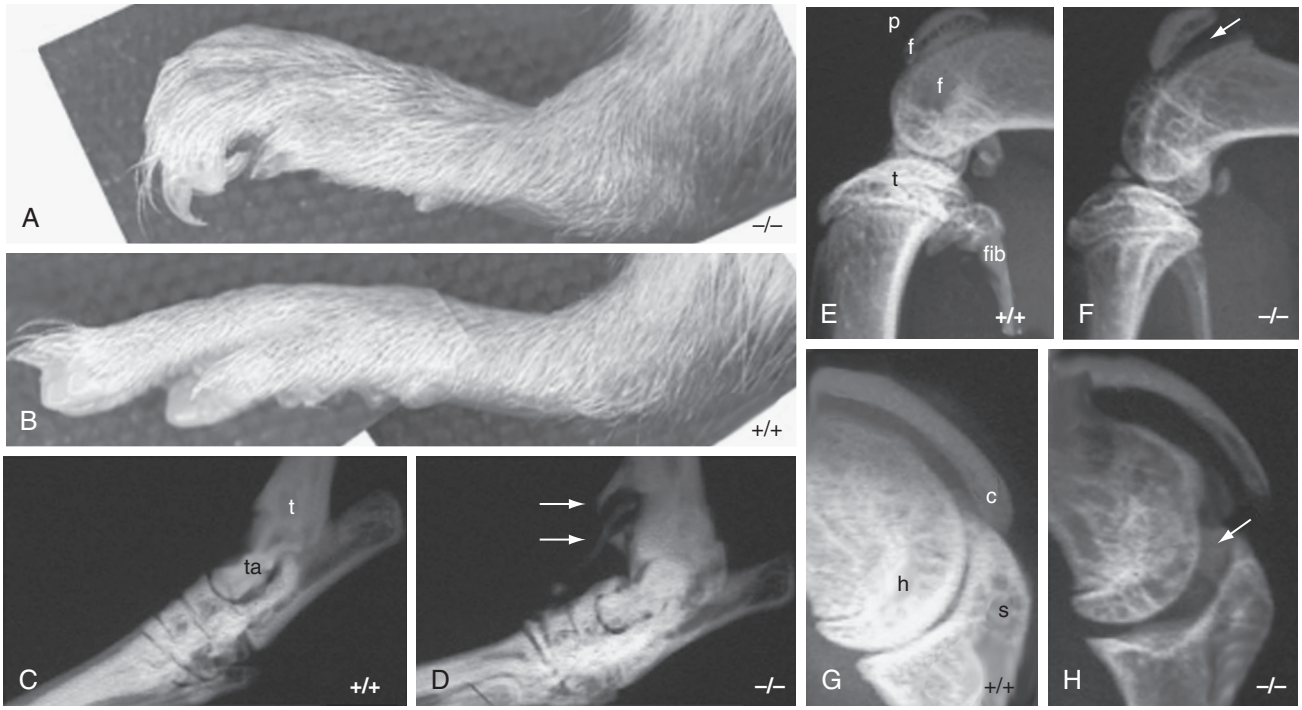

**Figure 2-8** Clinical appearance and radiographic changes in *Prg4*$^{-/-}$ mice. **A** and **B,** Photographs of the hind paws of 6-month-old *Prg4*$^{-/-}$ **(A)** and wild-type **(B)** mice. **Figure 2-10** Schematic representation of the formation of synovial fluid (SF). Many of the soluble components and proteins in SF exit the synovial subintimal microcirculation through pores or fenestrations in the vascular endothelium, then diffuse through the interstitium before entering the joint space. Synovial permeability to most small molecules is determined by a process of free diffusion through the double barrier of endothelium and interstitium, limited mainly by the intercellular space between synovial lining cells. Fat-soluble molecules can diffuse through, and between, cell membranes; their passage across the synovial surface is less restricted. Additional components, including hyaluronan and lubricin, are produced by synovial lining cells.

interstitium and that permeability to proteins is mainly determined by the microvascular endothelium. The synovium should not be regarded as simply an inert membrane but as a complex regulatory tissue system. The small physiologic molecules that traverse the endothelium of synovial blood vessels and diffuse through intercellular spaces of the synovial lining before entering the synovial fluid include water, glucose, and many other essential nutrients and waste tissue metabolites. Evidence suggests that passage of some solutes across the synovium is facilitated by specific transport systems that possibly provide a "pump" mechanism capable of moving water out of the joint space.

Plasma proteins are able to cross the endothelium, traversing the synovial interstitium and entering the synovial fluid. The efficiency of this process is determined by the molecular size of the protein and the diameter of the endothelial pores. Smaller proteins, such as albumin, enter easily, whereas larger molecules, such as fibrinogen, gain access with greater difficulty. In contrast, the clearance or removal of proteins and other synovial fluid constituents is unrestricted and considerably more efficient through lymphatic drainage. The synovial fluid concentration of any protein reflects the dynamic balance between ingress and egress at a given time. Because egress is more efficient than ingress, joint space pressure is normally subatmospheric. Negative intra-articular pressure is thought to be important in maintaining joint stability. The synovial fluid-to-serum ratio of plasma proteins is inversely related to the molecular size of the protein. When the joint becomes inflamed, greater endothelial permeability permits more profuse ingress of all proteins, and the most obvious changes are noted in the concentrations of larger molecules. Increased synovial fluid volume also reduces the stability of the joint.

In contrast to hydrophilic molecules, fat-soluble molecules can diffuse through and between cell membranes, and their passage across the synovial surface is less restricted. The entire surface area of the synovium is available to lipophilic molecules that diffuse into and out of the joint space. Physiologically, the most important fat-soluble molecules are the respiratory gases, oxygen and carbon dioxide. When the joint is inflamed, synovial fluid may exhibit low partial pressure of oxygen, high partial pressure of carbon dioxide, decreased pH, and increased lactate production.[82] The resultant hypoxia and acidosis can have serious implications for the synovial microcirculation and chondrocyte metabolism.

## Chondrocyte Nutrition

Another important function of synovium is to enhance the nutrition of chondrocytes, which reside in articular cartilage (see Chapter 3). Because articular cartilage is avascular, delivery of nutrients to chondrocytes and removal of metabolic breakdown products from the cartilage are believed to occur through synovial fluid and synovial tissue arterioles and venules, as well as through subchondral bone. Morphologic, physiologic, and pathologic studies have confirmed that solutes pass easily from the synovial fluid into cartilage and that cartilage does not survive without synovial fluid contact in vivo. Within the cartilage matrix, three potential mechanisms for nutrient transfer have been proposed: diffusion, active transport by chondrocytes, and pumping by intermittent compression of cartilage matrix. A large proportion of hyaline cartilage lies within 50 μm of a synovial surface and its rich supply of blood vessels. Chondrocytes are oxygen sensitive and are well adapted to living in hypoxic conditions. Low oxygen tension promotes expression of the chondrocyte phenotype and cartilage-specific matrix formation. Reactive oxygen species also may play a crucial role in the regulation of some normal chondrocytic activities, such as cell activation, proliferation, and matrix remodeling.

## CONCLUSION

The normal human synovial membrane is a highly specialized, multifunctional organ that is vital for mobility and survival. The intimal layer is composed of two distinct cell phenotypes with characteristics of macrophage and fibroblast lineages. Synovial macrophages express CD45, CD163 and CD97, CD68, neuron-specific esterase, and cathepsins B, L, and D. Cells expressing CD14 are rarely seen in the healthy intimal layer. FcγRIII (CD16), expressed by Kupffer cells of the liver and type II alveolar macrophages of the lung, is expressed on a subpopulation of synovial macrophages. Synovial macrophages also express the class II MHC molecule and play a central role in phagocytosis and in antigen-mediated immune responses.

Synovial intimal fibroblasts possess prominent synthetic capacity and produce the essential joint lubricants HA and lubricin. They also synthesize normal matrix components, including fibronectin, laminin, collagens, proteoglycans, lubricin, and other identified and unidentified proteins. They have the capacity to produce large quantities of metalloproteinases, metalloproteinase inhibitors, prostaglandins, and cytokines. Expression of selected adhesion molecules on synovial fibroblasts probably facilitates the trafficking of some cell populations, such as polymorphs, into synovial

fluid, and the retention of others, such as mononuclear leukocytes, within synovial tissue.

The subintimal layer is composed of a loose connective tissue matrix and contains branching blood and lymphatic vessels, a nerve supply, and a variety of resident cell populations, including infiltrating macrophages and fibroblasts. The nerve supply is important in regulating synovial blood flow. Lymphatic vessels allow egress of metabolic breakdown products from the synovium and synovial fluid. The structure of the subintimal layer varies according to the anatomic location and the local functional requirements.

Coordinated functions of the composite synovial membrane are essential for normal joint movement, formation of synovial fluid, nutrition of chondrocytes, and protection of cartilage. These functions must be preserved over a lifetime at multiple anatomic locations. Absence of essential constituents of synovial fluid, such as lubricin, or inadequate cartilage protection results in early articular malfunction, which may progress to variable degrees of joint failure. The characteristics of lubricin deficiency have been elegantly described in animal models and in humans. Additional studies may define novel clinical categories of degenerative polyarthritis that are associated with other specific disorders of synovial membrane function.

CHAPTER 3

# Cartilage and Chondrocytes

Mary B. Goldring • Kirsty L. Culley • Elisabeth Wondimu • Miguel Otero

**KEY POINTS**

- **Articular cartilage matrix is heterogeneous and contains numerous extra-cellular matrix (ECM) proteins, of which the large aggregating proteoglycan aggrecan and types II, IX, and XI collagen are the major constituents.**
- **The collagen network of cartilage confers tensile strength, and aggrecan provides resistance to compression.**
- **Adult articular chondrocytes are nonmitotic cells that survive at low oxygen tension in the absence of a vascular supply.**
- **In response to trauma or inflammation, the metabolic activity of the chondrocyte is increased in response to catabolic and anabolic factors that regulate remodeling of the ECM.**
- **Under physiologic conditions, the chondrocyte maintains low-turnover repair of proteoglycans, but the repair capacity, responses to anabolic factors, cell survival, and quality of the matrix decline with age.**

Hyaline cartilage, including the articular cartilage of diarthrodial joints, consists of a single cellular component, the chondrocyte, which is embedded in a unique and complex matrix. Adult articular chondrocytes are considered to be fully differentiated cells that maintain matrix constituents in a low-turnover state of equilibrium. Chondrocytes serve diverse functions during development and postnatal life. In the embryo, the chondrocyte arises from mesenchymal progenitors from diverse sources, including the cranial neural crest of the neural ectoderm, cephalic mesoderm, sclerotome of the paraxial mesoderm, and somatopleure of the lateral plate mesoderm, depending on the ultimate location of the cartilage. The chondrocyte synthesizes the templates, or cartilage anlagen, through a process termed *chondrogenesis*.

After mesenchymal condensation and chondroprogenitor cell differentiation, the chondrocytes undergo proliferation, terminal differentiation to chondrocyte hypertrophy, and apoptosis through a process termed *endochondral ossification*, whereby the hypertrophic cartilage is replaced by bone. A similar sequence of events occurs in the postnatal growth plate and leads to rapid growth of the skeleton. Processes that control the different stages of skeletal development are described in Chapter 1.

In adults, the anatomic distribution of cartilage is restricted primarily to the joints, trachea, and nasal septum, where the major function is structural support. In joints, cartilage has the additional function of providing low-friction articulation. Adult articular cartilage comprises a specialized matrix of collagens, proteoglycans, and other cartilage-specific and nonspecific proteins. Adult articular chondrocytes, which are remnants of the resting, or reserve, chondrocytes that laid down the original cartilage matrix during chondrogenesis, are inactive metabolically, partially because of the absence of a vascular supply and innervation in the tissue. The clinical importance of the adult chondrocyte resides in its capacity to respond to mechanical stimuli, growth factors, and cytokines that may influence normal homeostasis in a positive or negative manner. In persons with rheumatoid arthritis (RA), cartilage destruction occurs primarily in areas contiguous with the proliferating synovial pannus, although evidence indicates that the chondrocyte can respond to the inflammatory milieu and participate in degrading its own matrix. In persons with osteoarthritis (OA), the chondrocyte plays a key role by reacting to structural changes in the surrounding cartilage matrix through the production of catabolic cytokines and anabolic factors, which act in an autocrine-paracrine manner.[1,2] Nevertheless, the chondrocyte has limited capacity, which declines with age, to regenerate the normal cartilage architecture with zonal variations in the matrix network that was formed originally. This chapter focuses on the structure and function of normal articular cartilage and the role of the chondrocyte in maintaining cartilage homeostasis and responding to adverse environmental insults that may modify cartilage integrity.

## CARTILAGE STRUCTURE

Normal articular cartilage is a specialized tissue characterized macroscopically by its milky, shelled-almond (hyaline) appearance. It is an avascular tissue nourished by diffusion from the vasculature of the subchondral bone and from the synovial fluid. Articular cartilage is more than 70% water, and it is hypocellular compared with other tissues; chondrocytes constitute only 1% to 2% of its total volume. Most of the dry weight of cartilage consists of two components: type II collagen and the large aggregating proteoglycan, aggrecan. Several "minor" collagens and small proteoglycans also contribute to the unique structural organization of the cartilage matrix.[3,4]

Organic constituents represent only about 20% of the wet weight of cartilage. Collagen, primarily type II, accounts for approximately 15% to 25% of the wet weight and about half of the dry weight except in the superficial zone, where it represents most of the dry weight. Proteoglycans, primarily aggrecan, account for 10% of the wet weight and about 25% of the dry weight. The highly cross-linked type II

collagen–containing fibrils form a systematically oriented network that traps the highly negatively charged proteoglycan aggregates. Histochemical analysis of cartilage shows that proteoglycans can be stained reliably with Safranin O, Toluidine blue, or Alcian blue, although at low substrate concentrations, these methods are not stoichiometric.[5] Collagen also can be stained efficiently, but differentiation of collagen types requires immunostaining with specific antibodies.

Despite its thinness (≤7 mm) and apparent homogeneity, mature articular cartilage is a heterogeneous tissue with four distinct regions: (1) the superficial tangential (or gliding) zone, (2) the middle (or transitional) zone, (3) the deep (or radial) zone, and (4) the calcified cartilage zone, which is located immediately below the tidemark and above the subchondral bone (Figure 3-1).[4] In the superficial zone, the chondrocytes are flattened, with thin collagen fibrils in tangential array, a high concentration of the small proteoglycan decorin, and a low concentration of aggrecan. The middle zone, composing 40% to 60% of cartilage weight, consists of rounded chondrocytes surrounded by radial bundles of collagen fibrils that are thicker than in other zones. In the deep zone, chondrocytes frequently are grouped in columns or clusters.

Cell density progressively decreases from the surface to the deep zone, where it is one-half to one-third the density in the superficial zone; chondrocytes in the deep and middle zones have a cell volume that is twice that of superficial chondrocytes. Water is 75% to 80% of the wet weight in the superficial zone and progressively decreases to 65% to 70% with increasing depth. Compared with the middle and deep zones, greater amounts of collagen relative to proteoglycans are present in the superficial zone, and type I collagen may be present, in addition to type II collagen. With increasing depth, the proportion of proteoglycan increases to 50% of the dry weight in the deep zone. The calcified zone is formed as a result of endochondral ossification and persists after growth plate closure, with the histologically defined tidemark defining the boundary with the articular cartilage.[6] The calcified zone serves as an important mechanical buffer between uncalcified articular cartilage and subchondral bone (Figure 3-2).

The physical properties of articular cartilage are determined by the unique fibrillar collagen network, which

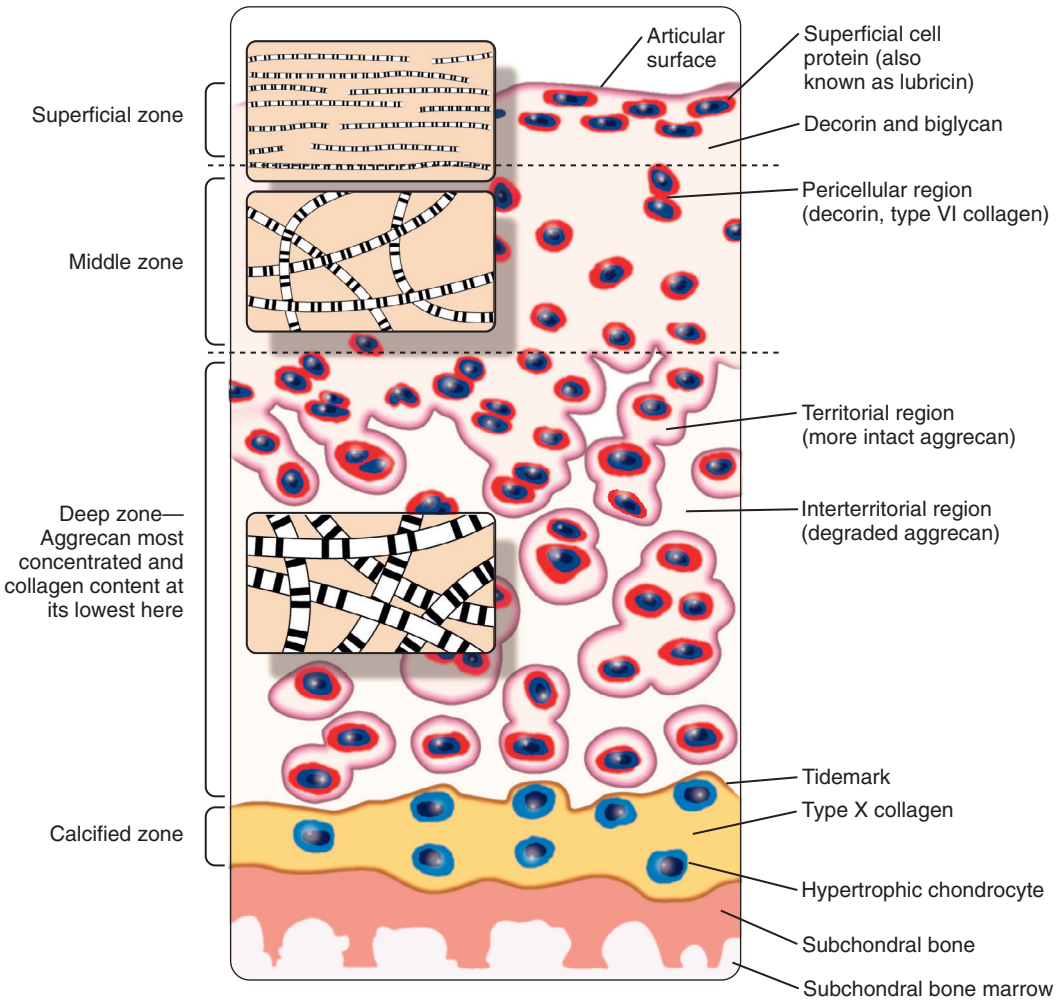

**Figure 3-1** The structure of human adult articular cartilage showing zones of cellular distribution and the pericellular, territorial, and interterritorial regions of matrix organization. Insets show the relative diameters and orientations of collagen fibrils in the different zones. The positions of the tidemark and subchondral bone and other special features of matrix composition also are noted. *(From Poole AR, Kojima T, Yasuda T, et al: Composition and structure of articular cartilage: a template for tissue repair.* Clin Orthop Relat Res *[391S]:S26–S33, 2001. Copyright Lippincott Williams & Wilkins.)*

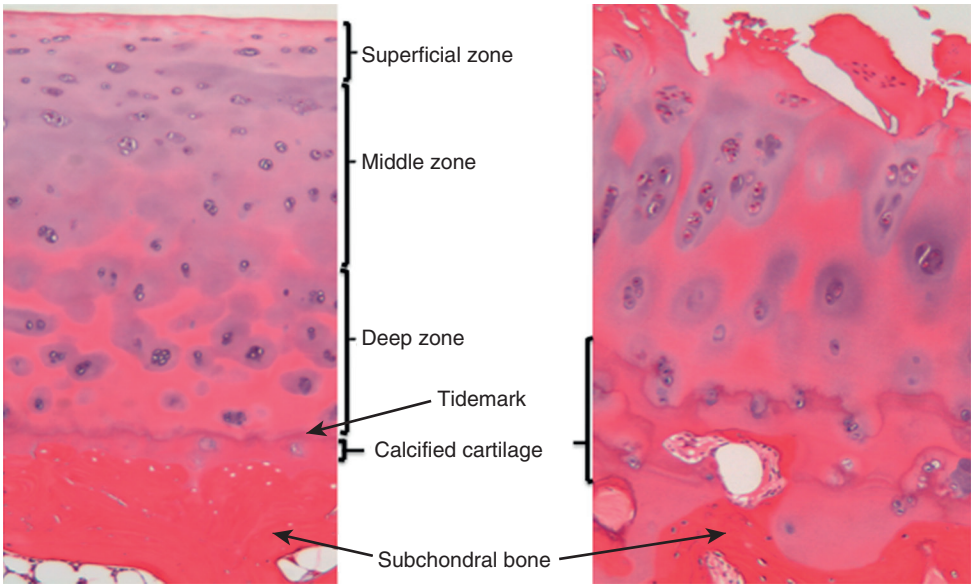

**Figure 3-2** The composition and cellular organization of healthy human adult articular cartilage *(left panel)* is more complex than it looks in this histologic section showing chondrocytes distributed in matrix with a homogeneous appearance and the clear demarcation (tidemark) between the articular cartilage and a thin zone of calcified cartilage next to the underlying subchondral bone. During the development of osteoarthritis, the normally quiescent chondrocytes become activated and undergo a phenotypic shift, resulting in surface fibrillation and degradation of cartilage matrix, the appearance of chondrocyte clusters, increased cartilage calcification associated with tidemark advancement, or duplication, and vascular penetration from the subchondral bone *(right panel). (Histology [Safranin O staining] courtesy Cecilia Dragomir, Hospital for Special Surgery, New York, NY; 10× magnification; modified from Goldring MB, Marcu KB: Epigenomic and microRNA-mediated regulation in cartilage development, homeostasis, and osteoarthritis.* Trends Mol Med *18:109–118, 2012.)*

provides tensile strength, interspersed with proteoglycan aggregates that bestow compressive resilience.[7,8] Proteoglycans are associated with large quantities of water bound to the hydrophilic glycosaminoglycan chains. This cartilaginous extra-cellular matrix (ECM), with its tightly bound water, provides a high degree of resistance to deformation by compressive forces. The capacity to resist compressive forces is associated with the ability to extrude water as the cartilage compresses. When compression is released, the proteoglycans (now depleted of balancing counter ions that were removed with the water) contain sufficient fixed charge to reabsorb osmotically the water and small solutes into the matrix, which then rebounds to its original dimensions.

## STRUCTURE-FUNCTION RELATIONSHIPS OF CARTILAGE MATRIX COMPONENTS

ECM components synthesized by chondrocytes include highly cross-linked fibrils of triple-helical type II collagen molecules that interact with other collagens, aggrecan, small proteoglycans, and other cartilage-specific and nonspecific matrix proteins (Table 3-1).[3,4,9] The importance of these structural proteins may be observed in heritable disorders, such as chondrodysplasias, or in transgenic animals in which mutations or deficiencies in cartilage genes result in cartilage abnormalities. Deficiencies or disruptions in genes that encode the cartilage-specific collagens result, in some cases, in premature OA.[10] Knowledge of the composition of the cartilage matrix has permitted the development of methods for identifying molecular markers in serum and synovial fluid that can be used to monitor changes in cartilage metabolism and to assess cartilage damage in OA or RA.[11] Changes in the structural composition of cartilage can markedly affect its biomechanical properties (see Chapter 6).

### Cartilage Collagens

The major component of the collagen network in adult articular cartilage is the triple-helical type II collagen molecule, which is composed of three identical α chains $(\alpha 1[II])_3$. These molecules are assembled in fibrils in a quarter-stagger array that can be observed by electron microscopy.[4,12] These fibrils are thinner than type I collagen–containing fibrils in skin because of the higher numbers of hydroxylysine residues that can form cross-links and the presence of other collagen and noncollagen components in the fibril. Type IIB collagen in articular cartilage is a product of alternative splicing and lacks a 69 amino acid, cysteine-rich domain of the amino-terminal propeptide, which is encoded by exon 2 in the human type II collagen gene *(COL2A1)*.[13] This domain is found in type IIA procollagen, which is expressed by chondroprogenitor cells during development, and in the amino propeptides of other interstitial collagen types, and it may play a feedback-inhibitory role in collagen biosynthesis.[14] The reappearance of type IIA collagen in the midzone pericellular matrix and type X collagen, the hypertrophic chondrocyte marker, in the deep zone of OA cartilage suggests reversion to a developmental phenotype in an attempt to repair the damaged matrix.

Although collagens VI, IX, XI, XII, and XIV are quantitatively minor components, they may have important structural and functional properties. Collagens IX and XI are relatively specific to cartilage, whereas collagens VI, XII, and XIV are widely distributed in other connective tissues.

**TABLE 3-1** Extra-cellular Matrix Components of Cartilage

| Molecule | Structure | Function and Location |
|---|---|---|
| **Collagens** | | |
| Type II | $[\alpha1(II)]_3$; fibril-forming | Tensile strength; major component of collagen fibrils |
| Type IX | [α1(IX)α2(IX)α3(IX)]; single CS or DS chain; α1(II) gene encodes α3(IX); FACIT | Tensile properties, interfibrillar connections; cross-links to surface of collagen fibril, NC4 domain projects into matrix |
| Type XI | [α1(XI)α2(XI)α3(XI)]; fibril-forming | Nucleation/control of fibril formation; within collagen fibril |
| Type VI | [α1(VI)α2(VI)α3(VI)]; microfibrils | Forms microfibrillar network; binds hyaluronan, biglycan, and decorin; pericellular |
| Type X | $[\alpha1(X)]_3$; hexagonal network | Support for endochondral ossification; hypertrophic zone and calcified cartilage |
| Type XII | $[\alpha1(XII)]_3$; FACIT large cruciform NC3 domain | Associated with type I collagen fibrils in perichondrium and articular surface |
| Type XIV | $[\alpha1(XIV)]_3$; FACIT | Associated with type I collagen; superficial zone |
| Type XVI | $[\alpha1(XVI)]_3$; FACIT | Integrates with collagen II/XI fibrils |
| Type XXVII | COL27A1: 156 kb, 61 exons | Fibril-forming; developing cartilage |
| **Proteoglycans** | | |
| Aggrecan | 255 kDa core protein; CS/KS side chains; C-terminal EGF and lectin-like domains | Compressive stiffness through hydration of fixed charge density; binding through G1 domain to HA stabilized by link protein |
| Versican | 265 to 370 kDa core protein; CS/DS side chains; C-terminal EGF, C-type lectin, and CRP-like domains | Low levels in articular cartilage throughout life; calcium-binding and selectin-like properties |
| Perlecan | 400 to 467 kDa core protein; HS/CS side chains; no HA binding | Cell-matrix adhesion; pericellular |
| Biglycan | 38 kDa; LRR core protein with two DS chains (76 kDa) | Binds collagen VI and TGF-β; pericellular |
| Decorin | 36.5 kDa; LRR core protein with one CS or DS side chain (100 kDa) | Controls size/shape of collagen fibrils, binds collagen II and TGF-β; interterritorial |
| Asporin | 40 kDa; LRR core protein; N-terminal extension of 15 aspartate residues | Binds collagen, modulates TGF-β function |
| Fibromodulin | 42 kDa; containing KS chains in central LRR region and N-terminal tyrosine sulfate domains | Same as decorin |
| Lumican | 38 kDa; structure similar to fibromodulin | Same as decorin |
| PRELP | 44 kDa; LRR core protein; proline-rich and arginine-rich N-terminal binding domain for heparin and HS | Mediates cell binding through HS in syndecan |
| Chondroadherin | 45 kDa; LRR core protein without N-terminal extension | Binding to cells via α2β1 integrin |
| **Other Molecules** | | |
| HA (hyaluronan) | 1000 to 3000 kDa | Retention of aggrecan within matrix |
| Link protein | 38.6 kDa | Stabilizes attachment of aggrecan G1 domain to HA |
| COMP | 550 kDa; five 110 kDa subunits; thrombospondin-like | Interterritorial in articular cartilage; stabilizes collagen network or promotes collagen fibril assembly; calcium binding |
| CMP (or matrilin-1); matrilin-3 | Three 50 kDa subunits with vWF and EGF domains | Tightly bound to aggrecan in immature cartilage |
| CILP | 92 kDa; homology with nucleotide pyrophosphohydrolase without active site | Restricted to middle/deep zones of cartilage; increase in early and late OA |
| Glycoprotein (gp)-39, YKL-40, or chitinase 3-like protein 1 (CH3L1) | 39 kDa; chitinase homology | Marker of cartilage turnover; chondrocyte proliferation; superficial zone of cartilage |
| Fibronectin | Dimer of 220 kDa subunits | Cell attachment and binding to collagen and proteoglycans; increased in OA cartilage |
| Tenascin-C | Six 200 kDa subunits forming hexabrachion structure | Binds syndecan-3 during chondrogenesis; angiogenesis |
| SZP, lubricin, or PRG 4 | 225 kDa, 200 nm length | Joint lubrication; superficial zone only |

**TABLE 3-1** Extra-cellular Matrix Components of Cartilage—cont'd

| Molecule | Structure | Function and Location |
|---|---|---|
| **Membrane Proteins** | | |
| CD44 | Integral membrane protein with extra-cellular HS/CS side chains | Cell-matrix interactions; binds HA |
| Syndecan-1, -3, -4 | N-terminal HS attachment site; cytoplasmic tyrosine residues | Syndecan-3 is receptor for tenascin-C during cartilage development; cell-matrix interactions |
| Annexin V (anchorin CII) | 34 kDa; homology to calcium-binding proteins calpactin and lipocortin | Cell surface attachment to type II collagen; calcium binding |
| Integrins (α1, α2, α3, α5, α6, α10; β1, β3, β5) | Two noncovalently linked transmembrane glycoproteins (α and β subunits) | Cell-matrix binding: α1β1/collagen I or VI, α2β1 or α3β1/collagen II, α5β1/fibronectin; intra-cellular signaling |
| Discoidin domain receptor 2 | Receptor tyrosine kinase | Binds native type II collagen fibrils; Ras/ERK signaling |
| TRPV4 | $Ca^{2+}$ channel | Mechanosensor |
| Connexin 43 | ATP release channel | Mechanosensor; primary cilia |

ATP, Adenosine triphosphate; CILP, cartilage intermediate layer protein; CMP, cartilage matrix protein; COMP, cartilage oligomeric matrix protein; CRP, complement regulatory protein; CS, chondroitin sulfate; DS, dermatan sulfate; EGF, epidermal growth factor; FACIT, fibril-associated collagens with interrupted triple helices; HA, hyaluronic acid; HS, heparan sulfate; KS, keratan sulfate; LRR, leucine-rich repeat; NC, noncollagen; OA, osteoarthritis; PRELP, proline-rich and arginine-rich end leucine-rich repeat protein; PRG, proteoglycan; SZP, superficial zone protein; TGF-β, transforming growth factor-β; TRPV4, transient receptor potential vanilloid 4; vWF, von Willebrand factor.

Collagen VI is present as microfibrils in the pericellular matrix; it may play a role in cell attachment and interacts with other matrix proteins, such as hyaluronan, perlecan, biglycan, monomers or small aggregates of aggrecan, and type IX collagen, which are located there exclusively or at higher amounts than in the interterritorial matrix.[15] Small amounts of collagen III are present in cartilage, and collagens VI and III may increase in OA cartilage.[3]

Type IX collagen is a proteoglycan and a collagen because it contains a chondroitin sulfate chain attachment site in one of the noncollagen domains. The helical domains of the type IX collagen molecule form covalent cross-links with type II collagen telopeptides and are attached to the fibrillar surface, as observed by the electron microscope. Type IX collagen may function as a structural intermediate between type II collagen fibrils and the proteoglycan aggregates, serving to enhance the mechanical stability of the fibril network and resist the swelling pressure of the trapped proteoglycans. Destruction of type IX collagen accelerates cartilage degradation and loss of function.

The α3 chain of type XI collagen has the same primary sequence as the α1(II) chain, and the heterotrimeric type XI collagen molecule is buried in the same fibril as type II collagen. Type XI collagen may have a role in regulating fibril diameter. The more recently discovered nonfibrillar fibril-associated collagens with interrupted triple helices (FACIT), XII and XIV, which are structurally related to type IX collagen, do not form fibrils by themselves but co-aggregate with fibril-forming collagens and modulate the packing of collagen fibers through domains projecting from their surfaces.

## Cartilage Proteoglycans

The major proteoglycan in articular cartilage is the large aggregating proteoglycan, or aggrecan, which consists of a core protein of 225 to 250 kDa with covalently attached side chains of glycosaminoglycans, including approximately 100 chondroitin sulfate chains, 30 keratan sulfate chains, and shorter *N*-linked and *O*-linked oligosaccharides.[3] Link protein, a small glycoprotein, stabilizes the noncovalent linkage between aggrecan and hyaluronic acid (also called *hyaluronan*) to form the proteoglycan aggregate that may contain 100 aggrecan monomers. The G1 and G2 N-terminal globular domains of aggrecan and its C-terminal G3 domain have distinct structural properties that function as integral parts of the aggrecan core protein and contribute cleavage products that accumulate with age or in OA. The G2 domain is separated from G1 by a linear interglobular domain and has two proteoglycan tandem repeats. The G3 domain contains sequence homologies to epidermal growth factor, lectin, and complement regulatory protein, and it participates in growth regulation, cell recognition, intra-cellular trafficking, and the recognition, assembly, and stabilization of the ECM. About half of the aggrecan molecules in adult cartilage lack the G3 domain, probably as a result of proteolytic cleavage during matrix turnover. Small quantities of other large proteoglycans are found in cartilage, including versican, which forms aggregates with hyaluronic acid, and perlecan, which is nonaggregating; however, these proteoglycans function primarily during skeletal development, when versican is expressed in prechondrogenic condensations and perlecan is expressed in the cartilage anlagen after expression of type II collagen and aggrecan.[16,17]

The nonaggregating small proteoglycans are not specific to cartilage, but in cartilage they serve specific roles in matrix structure and function, primarily by modulating collagen-fibril formation.[3,18] Of the more than 10 leucine-rich repeat (LRR) proteoglycans discovered thus far, only osteoadherin is not present in cartilage. The 24 amino acid central LRR domain is conserved, but the N-terminal and C-terminal domains have patterns of cysteine residues involved in intrachain disulfide bonds that distinguish the four subfamilies: (1) biglycan, decorin, fibromodulin, and lumican; (2) keratocan and proline and arginine-rich end

leucine-rich repeat protein (PRELP); (3) chondroadherin; and (4) epiphycan/PG-Lb and mimecan/osteoglycin. Biglycan may have one or two glycosaminoglycan chains—chondroitin sulfate and/or dermatan sulfate—attached near the N-terminus through two closely spaced serine-glycine dipeptides. Decorin contains only one chondroitin sulfate or dermatan sulfate chain. Fibromodulin and lumican contain keratan sulfate chains linked to the central domain of the core protein and several sulfated tyrosine residues in the N-terminus. Negatively charged glycosaminoglycan side chains contribute to the fixed charge density of the matrix and, together with the highly anionic tyrosine-sulfation sites, permit multiple-site linkage between adjacent collagen fibrils, stabilizing the network. Decorin, the most extensively studied LRR proteoglycan, binds to collagens II, VI, XII, and XIV and to fibronectin and thrombospondin. Biglycan, decorin, and fibromodulin bind transforming growth factor (TGF)-β and the epidermal growth factor receptor and may modulate growth, remodeling, and repair. PRELP and chondroadherin may regulate cell-matrix interactions through binding to syndecan and α2β1 integrin.

### Other Extra-cellular Matrix and Cell Surface Proteins

Several other noncollagenous matrix proteins may play important roles in determining cartilage matrix integrity.[19] Cartilage oligomeric matrix protein (COMP), a member of the thrombospondin family, is a disulfide-bonded, pentameric, 550 kDa, calcium-binding protein that constitutes approximately 10% of the noncollagenous, nonproteoglycan protein in normal adult cartilage. COMP is located in the interterritorial matrix of adult articular cartilage, where it interacts with the COL3 and NC4 domains of type IX collagen that protrude from the fibril, stabilizing the collagen network. COMP is pericellular in the proliferating region of the growth plate, where it may have a role in cell-matrix interactions.[20] The cartilage matrix protein (or matrilin-1) and matrilin-3 are expressed in cartilage at certain stages of development. Matrilin-1 is present in the pericellular matrix of adult articular cartilage and matrilin-1, -2, and -3 may be upregulated in articular cartilage in the presence of OA.[21]

Tenascin-C, a glycoprotein that is regulated in development, is characteristic of nonossifying cartilage. Similar to fibronectin, alternative splicing of tenascin-C messenger RNA (mRNA) gives rise to different protein products at different stages of chondrocyte differentiation. Both proteins are increased in OA cartilage and may serve specific functions in remodeling and repair.[22] The cartilage intermediate-layer protein (CILP) is expressed by chondrocytes in the middle to deep zones of articular cartilage as a precursor protein. When cleaved during secretion, CILP has structural similarities with nucleotide pyrophosphohydrolase, although it lacks the catalytic site, and it may play a role in pyrophosphate metabolism and calcification.[23] Asporin is related to decorin and biglycan and, similar to those other LRR proteins, may interact with and sequester growth factors such as TGF-β.[24] YKL-40/HC-gp39, also known as *chitinase 3–like protein 1*, is found only in the superficial zone of normal cartilage and stimulates proliferation of chondrocytes and synovial cells.[25] Chitinase 3–like protein 1 is induced by inflammatory cytokines and may function as a feedback regulator because it inhibits cytokine-induced cellular responses. Synthesis or release of these proteins or fragments is often increased in cartilage that is undergoing repair or remodeling, and they have been investigated as markers of cartilage damage in arthritis.

## STRUCTURE, CLASSIFICATION, AND NORMAL FUNCTION OF CHONDROCYTES

### Structure

The characteristic feature of the chondrocyte embedded in cartilage matrix is its rounded or polygonal structure. The exception occurs at tissue boundaries, such as the articular surfaces of joints, where chondrocytes may be flattened or discoid. Intra-cellular features, including a rough endoplasmic reticulum, a juxtanuclear Golgi apparatus, and deposition of glycogen, are characteristic of a synthetically active cell. The cell density of full-thickness, human, adult, femoral condyle cartilage is maintained at 14.5 (±3.0) × $10^3$ cells/$mm^2$ from age 20 to 30 years. Although senescence of chondrocytes occurs with aging, mitotic figures are not observed in normal adult articular cartilage.

The structure, density, and synthetic activity of an adult chondrocyte vary according to its position within the different zones of articular cartilage.[4] In the region of highest cell density, the superficial zone, cells are flattened and are oriented parallel to the surface, along with the collagen fibers. Chondrocytes within the middle zone appear larger and more rounded and display a random distribution within the matrix, where the collagen fibers also are more randomly arranged. Chondrocytes in the deeper zones form columns that, along with the collagen fibers, are oriented perpendicular to the cartilage surface. Chondrocytes may exhibit different behaviors depending on their position within the different layers, and these zonal differences in synthetic properties may persist in primary chondrocyte cultures. The primary cilia are important for spatial orientation of cells in developing growth plate and are sensory organelles in chondrocytes. Primary cilia are centers for wingless type (Wnt) and hedgehog signaling and contain mechanosensitive receptors, including the transient receptor potential vanilloid 4 (TRPV4), a $Ca^{2+}$ channel, and connexin 43, an adenosine triphosphate (ATP) release channel.[26,27]

### Classification: Cell Origin and Differentiation

Chondrocytes arise in the embryo from mesenchymal origin during *chondrogenesis*, which is the earliest phase of skeletal development involving mesenchymal cell recruitment, migration, and condensation and differentiation of mesenchymal chondroprogenitor cells.[28,29] As described in detail in Chapter 1, chondrogenesis results in the formation of cartilage anlagen, or templates, at sites where skeletal elements form. This process is controlled by cell-cell and cell-matrix interactions and by growth and differentiation factors that initiate or suppress cellular signaling pathways and transcription of specific genes in a temporospatial manner (Figure 3-3).[30]

Vertebrate limb development is controlled by interacting patterning systems involving fibroblast growth factor (FGF),

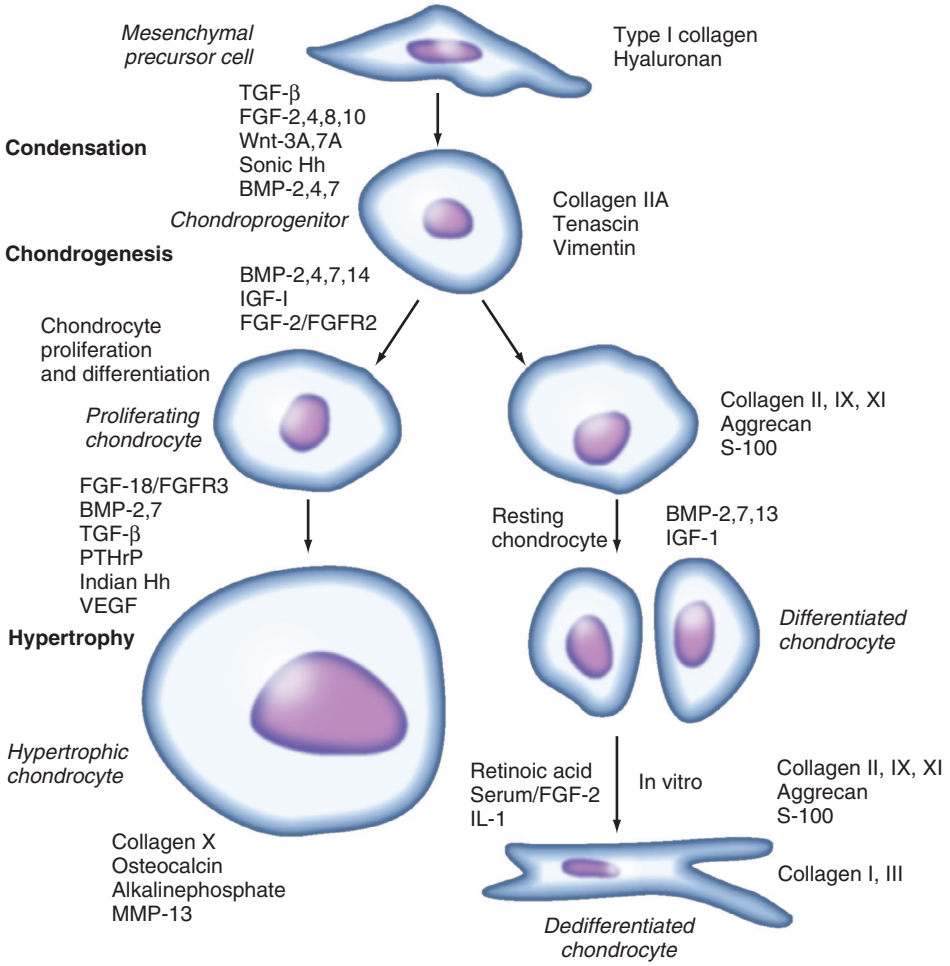

**Figure 3-3** Schematic representation of cellular phenotypes associated with developmental fates during condensation, chondrogenesis, chondrocyte proliferation, differentiation, and hypertrophy. Some of the regulatory factors active at different stages are listed to the left of the arrows. The major extra-cellular matrix genes are listed to the right of each cell type in which they are differentially expressed. BMP, Bone morphogenetic protein; FGF, fibroblast growth factor; Hh, hedgehog; IGF, insulin-like growth factor; IL-1, interleukin-1; MMP, matrix metalloproteinase; PTHrP, parathyroid hormone–related protein; TGF-β, transforming growth factor-β; VEGF, vascular endothelial growth factor; Wnt, wingless type.

hedgehog, bone morphogenetic protein (BMP), TGF-β, and Wnt pathways.[31-34] Wnt signaling, via the canonical β-catenin pathway and activation of T cell factor (TCF)/Lef transcription factors, functions in a cell-autonomous manner to induce osteoblast differentiation and suppress chondrocyte differentiation in early chondroprogenitors. During chondrogenesis, Wnt/β-catenin acts at two stages: at low levels to promote chondroprogenitor differentiation, and later at high levels to promote chondrocyte hypertrophic differentiation and subsequent endochondral ossification. The transcription factor, Sry-type high-mobility group box 9 (Sox9), is an early marker of the differentiating chondrocyte that is required for the onset of expression of type II collagen, aggrecan, and other cartilage-specific matrix proteins, such as type IX collagen.[32] Two other members of the SOX family, L-Sox5 and Sox6, are not present in early mesenchymal condensations but are required during overt chondrocyte differentiation, forming heterodimers that induce transcription more efficiently than Sox9 by itself. Expression of SOX proteins depends on signaling through mammalian homologs of *Drosophila* mothers against decapentaplegic (SMADs), which are functionally redundant and active in differentiating chondrocytes. Other transcription factors such as Gata4/5/6 and Nkx3.2 may interact directly or indirectly with Sox9 to upregulate the expression of *COL2A1* aggrecan (*ACAN*) and other cartilage-specific genes at early stages of chondrogenesis.[35]

In the embryonic or postnatal epiphyseal growth plates, molecules that promote matrix remodeling and angiogenesis facilitate endochondral ossification, whereby bone replaces the calcified cartilaginous matrix in the hypertrophic zone (see Chapter 1). Differentiated chondrocytes that remain in the reserve, or resting, zone become the cartilage elements in articular joints, or they can proliferate and undergo the complex process of terminal differentiation to hypertrophy marked by type X collagen. Indian hedgehog and parathyroid hormone–related protein (PTHrP) transiently induce proliferation and repress differentiation, determining the number of cells that enter the hypertrophic maturation pathway. The Runt domain transcription factor, Runx2 (also known as *core binding factor* or Cbfa1), serves as a positive regulatory factor in chondrocyte maturation to the hypertrophic phenotype and subsequent osteogenesis.[36] Runx2 is expressed in the adjacent perichondrium and in

prehypertrophic chondrocytes, but less in late hypertrophic chondrocytes, and is required for expression of type X collagen and other markers of terminal differentiation.[28,35]

Numerous other transcription factors positively or negatively regulate chondrocyte terminal differentiation by controlling, in part, the expression or activity of Runx2.[35,36] BMP-induced Smad1 and interactions between Smad1 and Runx2 are required for the induction of chondrocyte hypertrophy. Histone deacetylase 4 (HDAC4), which is expressed later in prehypertrophic chondrocytes, prevents premature chondrocyte hypertrophy by interacting with Runx2 and inhibiting its activity.[37] The hypoxia-inducible factor (HIF)-1α contributes to chondrocyte survival during hypertrophic differentiation, partially because of its regulation of vascular endothelial cell growth factor (VEGF) expression, and it prevents premature hypertrophy by directly suppressing Runx2 activity. The transcription factors involved in regulating gene expression during late-stage hypertrophy, in addition to Runx2, include Runx3, myocyte enhancer factor (MEF) 2C and 2D, Foxa2 and FoxA3, and Zfp521.[28,35]

One major function of the chondrocyte is growth of the skeleton through increased cell proliferation, production of ECM, and cell volume through hypertrophy. Lineage tracing studies indicate that Sox9-expressing cells are precursors for both articular and growth plate chondrocytes. Furthermore, cells expressing *Tgfbr2*, the gene encoding the TGF-β receptor II in the interzone, can be traced to synovial lining, superficial meniscus, and ligaments and may persist as reserve progenitor cells that could later participate in regeneration. Finally, Gdf5, matrilin-1, and PTHrP appear to specify the eventual border between the articular cartilage surface and the joint space.[29] After cessation of growth, the resting chondrocyte remains as part of the supporting structures in articular, tracheal, and nasal cartilages, indicating that the fate of a chondrocyte depends on origin and location.[31]

## Normal Function of the Adult Articular Chondrocyte

The mature articular chondrocyte embedded in its ECM is a resting cell with no detectable mitotic activity and a low rate of synthetic activity. Because articular cartilage is not vascularized, the chondrocyte must rely on diffusion from the articular surface or subchondral bone for exchange of nutrients and metabolites. Chondrocytes maintain active membrane transport systems for exchange of cations, including $Na^+$, $K^+$, $Ca^{2+}$, and $H^+$, whose intra-cellular concentrations fluctuate with load and changes in the composition of the cartilage matrix. The chondrocyte cytoskeleton is composed of actin, tubulin, and vimentin filaments, and the composition of these filament systems varies in the different cartilage zones.

Chondrocyte metabolism operates at low oxygen tension within the cartilage matrix, ranging from 10% at the surface to less than 1% in the deep zone. The consumption of oxygen by cartilage on a per-cell basis is only 2% to 5% of that in the liver or kidney, although the amounts of lactate produced are comparable. Chondrocytes do not normally contain abundant mitochondria, energy metabolism depends strongly on the glucose supply, and the energy requirements may be modulated by mechanical stress. Glucose serves as the major energy source for chondrocytes and as an essential precursor for glycosaminoglycan synthesis. Facilitated glucose transport in chondrocytes is mediated by several distinct glucose transporter proteins (GLUTs) that may be constitutively expressed (GLUT3 and GLUT8) or induced by cytokines (GLUT1 and GLUT6). Proteomic studies of chondrocytes have identified intra-cellular proteins known to be involved in cell organization, energy protein fate, metabolism, and cell stress. The relative expression of these proteins may determine the capacity of chondrocytes to survive in cartilage matrix and to modulate metabolic activity in response to environmental changes.

When cultured in a range of oxygen tensions between severe hypoxia (0.1% oxygen) and normoxia (21% oxygen), chondrocytes adapt to low oxygen tension by upregulating HIF-1α. Hypoxia via HIF-1α can stimulate chondrocytes to express GLUTs, angiogenic factors such as VEGF, and numerous genes associated with cartilage anabolism and chondrocyte differentiation.[38] In the growth plate, hypoxia and HIF-1α are associated with type II collagen production. HIF-1α is expressed in normal and OA articular cartilage, where it maintains tonic activity during physiologic hypoxia in the deeper layers associated with increased proteoglycan synthesis. In contrast to other tissues, however, HIF-1α is not completely degraded in cartilage, when normoxic conditions are applied. Long-term systemic hypoxia (13%) may downregulate collagen and aggrecan gene expression in articular cartilage, whereas hyperoxia (55% oxygen) may increase the breakdown of cartilage collagens in articular cartilage in the presence of vascularized rheumatoid synovium. By modulating the intra-cellular expression of survival factors such as HIF-1α, chondrocytes have a high capacity to survive in the avascular cartilage matrix and to respond to environmental changes.[38] Recent studies indicate that another hypoxia-inducible factor, HIF-2α, can become activated by pro-inflammatory cytokines and stress in the avascular, hypoxic environment of articular cartilage.[39,40]

The chondrocyte maintains a steady-state metabolism secondary to equilibrium between anabolic processes and catabolic processes that results in the normal turnover of matrix molecules. In normal adult articular cartilage, the turnover of matrix components is low. The turnover of collagen has been estimated to occur with a half-life greater than 100 years. In contrast, glycosaminoglycan constituents on the aggrecan core protein are more readily replaced; the half-life of aggrecan subfractions has been estimated to range from 3 months to 24 years. Other cartilage ECM components including biglycan, decorin, COMP, tenascins, and matrilins that were incorporated previously into the matrix during development also may be synthesized by chondrocytes under low-turnover conditions. Regional differences in the remodeling activities of chondrocytes have been noted, however, and matrix turnover may be more rapid in the immediate pericellular zones. The metabolic potential of these cells is indicated by their capacity to proliferate in culture and to synthesize matrix proteins after enzymatic release from the cartilage even of elderly persons.

The complex composition of the articular cartilage matrix is more difficult for the chondrocyte to replicate if

severe damage to the collagen network occurs. During initial stages of OA, chondrocytes in vivo respond to structural changes in the surrounding cartilage matrix by increasing cell proliferation and synthesis of matrix proteins, proteinases, and anabolic and catabolic factors. The aberrant behavior of OA chondrocytes is reflected in the appearance of fibrillations, matrix depletion, cell clusters, and changes in quantity, distribution, or composition of matrix proteins. Evidence of phenotypic modulation is reflected in increases in collagens I and III and the appearance of the hypertrophic chondrocyte marker, type X collagen, and other markers of terminal differentiation, suggesting recapitulation of a developmental program.[2,41]

Genomic and proteomic analyses of global gene expression in cartilage have revealed increased anabolism reflected in increased levels of *COL2A1* and other cartilage-specific mRNAs in late OA, but also noncartilage collagens and other matrix proteins. Nevertheless, the capacity of the adult articular chondrocyte to regenerate the normal cartilage matrix architecture is limited, and the damage becomes irreversible if the destructive process is not interrupted.

## CULTURE MODELS FOR STUDYING CHONDROCYTE METABOLISM

Primary cultures of articular chondrocytes have served as useful models for studying the mechanisms controlling responses to growth factors and cytokines.[42,43] A challenge to researchers in cartilage biology is the maintenance of chondrocyte structure and cartilage-specific gene expression during in vitro studies. In confluent primary monolayer cultures, chondrocytes maintain a rounded, polygonal structure (Figure 3-4), but progressive loss of cartilage phenotype is seen with the passage of time and after subculture. High-density cultures maintain the gene expression and synthesis of cartilage-specific matrix proteins until they are subcultured, although gene expression of type II collagen is generally more labile than that of aggrecan. During this loss of phenotype or dedifferentiation, chondrocytes lose their rounded, polygonal structure and express some, but not all, characteristics of the fibroblast phenotype, such as type I collagen. It is possible to expand cultures through a limited number of subcultures and to "redifferentiate" the cells in three-dimensional culture systems, in which chondrocytes regain structure; cessation of proliferation is associated with increased expression of cartilage-specific matrix proteins. Alternatively, explant cultures of articular cartilage in which chondrocytes remain encased within their own ECM have been used as in vitro models to study cartilage biochemistry and metabolism, as described in the next section.

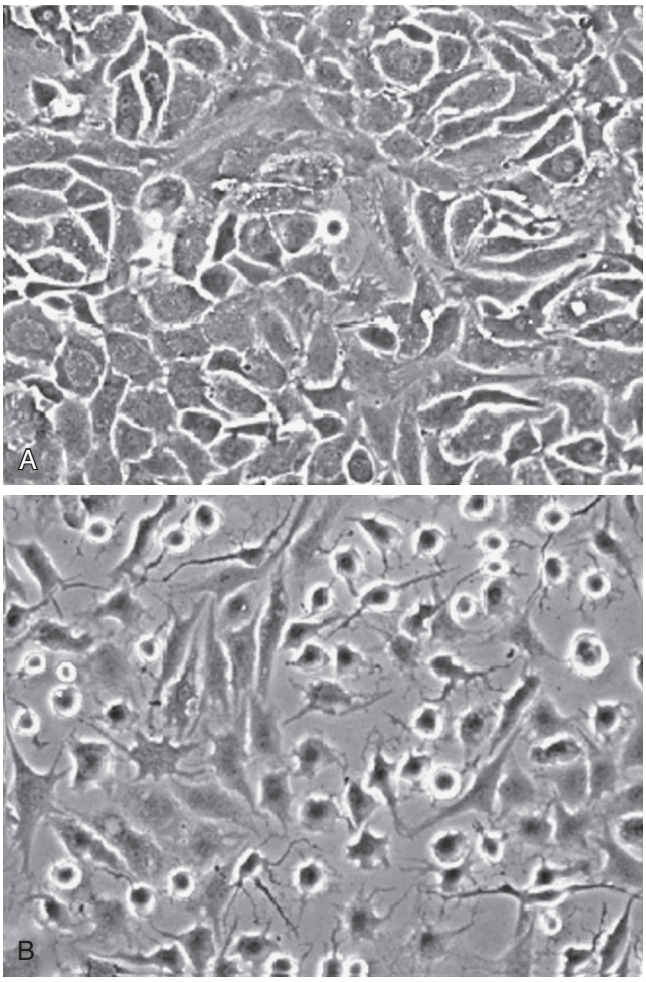

**Figure 3-4** Structure of human articular chondrocytes grown in monolayer culture on plastic. Chondrocytes were isolated from articular cartilage and cultured in growth medium containing 10% fetal calf serum until confluent. The cultures were changed to serum-free defined medium, IL-1β was added the next day, and incubation was continued for 24 hours. **A,** Untreated chondrocytes display the characteristic cobblestone structure. **B,** IL-1β–treated cultures respond with a dramatic morphologic change.

### Articular Chondrocytes

#### Cartilage Explant (Organ) Cultures

Based on the pioneering work of Dame Honor Fell, who showed that it was possible to maintain pieces of cartilage in culture, the explant culture system was developed to characterize chondrocyte function in cartilage from various species, including humans, at different ages. Early work in bovine cartilage established the mechanisms of biosynthesis of cartilage proteoglycans under the influence of different serum concentrations and determined the turnover rate whereby the chondrocyte could maintain the balance between anabolic and catabolic pathways. Methods developed for measuring the proteoglycan content in cartilage, such as incorporation of sulfate $^{35}S$ into newly synthesized proteoglycans or spectrophotometric quantitation of Alcian blue staining, have been used widely as standard assays for assessing cartilage metabolism. Cartilage organ cultures also maintain constant levels of type II collagen during several weeks of culture, along with the characteristic structure and banding pattern of collagen fibrils. These cultures have been useful for studying the regulation of cartilage matrix synthesis and degradation by proteinases, inflammatory cytokines, retinoic acid, and anabolic growth factors.[44]

#### Monolayer Cultures

Primary monolayer cultures of chondrocytes isolated from young animals that maintain the cartilage-specific phenotype at least throughout primary culture are easily obtained

and have been used widely to assess differentiated chondrocyte functions. When chondrocytes are isolated from their matrix and cultured in monolayer, they adhere to the culture dish and readily respond to serum growth factors that stimulate proliferation of normally quiescent cells. Freshly isolated human articular or costal chondrocytes express cartilage-specific type II collagen and continue to do so for several days to weeks in primary monolayer culture. In addition to cartilage-specific collagens and aggrecan, chondromodulin and protein S-100 are useful markers expressed in primary chondrocyte cultures. Identification of cell surface markers that determine chondrogenic capacity may enable the enrichment of subpopulations for further characterization.

Early attempts to culture chondrocytes from various animal and human sources were frustrated by the tendency of these cells to acquire a fibroblast-like structure associated with the appearance of type I collagen synthesis. When plated at high density, the cells maintain a polygonal, although flattened, structure. At low plating densities, with prolonged culture, and upon expansion in serial subculture, the cells gradually assume a more elongated, "fibroblast-like" structure. Early work suggested that this change in structure is associated with loss of phenotype, whereby the synthesis of cartilage-specific matrix molecules, such as type II collagen and aggrecan, decreases or disappears. This "dedifferentiated phenotype," which has been described thus far only in vitro, is marked by the appearance of synthesis of type I and type III collagens, and it can be accelerated by plating the cells at low densities or by treating with cytokines such as interleukin (IL)-1 or retinoic acid. The substrate on which chondrocytes are plated can influence the differentiation capacity of articular chondrocytes.[45] Culture expansion in medium with low concentration of glucose can also preserve the chondrocyte phenotype in monolayer and promote the capacity of chondrocytes to form a cartilage-like matrix in three-dimensional culture.[43]

The use of chondrocytes of adult human origin in studies related to the pathogenesis of joint disease has been problematic because the source of the cartilage cannot be controlled, sufficient numbers of cells are not readily obtained through random operative procedures, and the phenotypic stability of adult human chondrocytes is lost more quickly upon expansion in serial monolayer cultures than in cells of juvenile human or embryonic or postnatal animal origin. Serum-free defined media of varying compositions, but usually including insulin, have been used, frequently in combination with monolayer and other culture systems, as mentioned in the next section.

### Three-Dimensional Culture Systems

Early studies showed that the phenotype can be maintained if isolated chondrocytes are placed in suspension cultures in spinner flasks or in dishes coated with nonadherent substrates. Freshly isolated or subcultured chondrocytes also can be embedded in three-dimensional matrices, such as collagen gels or sponges, agarose, or alginate.[42] In these three-dimensional matrices, chondrocytes have a normal spherical shape, synthesize and secrete abundant cell-associated ECM components, and may maintain phenotypic stability for several months. Because articular chondrocytes are unable to proliferate in suspension or three-dimensional culture, expansion in monolayer culture followed by transfer to alginate culture, for example, has been used as a strategy to obtain sufficient numbers of differentiated chondrocytes for study. After prolonged culture in monolayer, however, the chondrogenic potential of dedifferentiated chondrocytes may irreversibly be lost.

The high-density pellet culture system, which was originally developed to study growth plate hypertrophy, has been used as a three-dimensional model because it permits articular chondrocytes to deposit a well-organized ECM that contains type II collagen and aggrecan.[45,46] These pellet cultures show *phenotypic plasticity*, comparable with that of mesenchymal stem cells undergoing chondrogenesis, by recapitulating aspects of chondrocyte hypertrophy.[43,46] Isolated chondrons containing one or more chondrocytes within a capsule of pericellular matrix also have been used for in vitro studies of chondrocyte metabolism within a three-dimensional environment.[47]

## INTERACTIONS OF CHONDROCYTES WITH THE EXTRA-CELLULAR MATRIX

Chondrocytes in vivo respond to structural changes in the cartilage ECM. The ECM not only provides a framework for chondrocytes suspended within it, but its constituents interact with cell surface receptors and provide signals that regulate many chondrocyte functions (Figure 3-5).[48]

### Integrins

The most prominent of the ECM receptors are the integrins, which bind specifically to different cartilage matrix components and induce the formation of intra-cellular signaling complexes that regulate cell proliferation, differentiation, survival, and matrix remodeling. Integrins also may serve as mechanoreceptors that mediate responses to normal and abnormal loading of cartilage.[49] Chondrocytes express many different integrins that interact with cartilage ECM ligands, although most are not specific to this cell type. They include integrins that are receptors for collagen ($\alpha1\beta1$, $\alpha2\alpha1$, $\alpha3\alpha1$, and $\alpha10\alpha1$), fibronectin ($\alpha5\alpha1$, $\alpha v\alpha3$, and $\alpha v\alpha5$), and laminin ($\alpha6\alpha1$). The integrin $\alpha1\alpha1$ has broader ligand specificity than the other collagen-binding integrins and mediates chondrocyte adhesion to pericellular type VI collagen and to the cartilage matrix protein, matrilin-1. The $\alpha2\alpha1$ integrin also binds to chondroadherin. The $\alpha v$-containing integrins bind to vitronectin and osteopontin, in addition to serving as alternative fibronectin receptors. The $\alpha5\alpha1$ and $\alpha v\alpha3$ integrins serve as receptors for different conformations of COMP.

Because $\alpha1\alpha1$, $\alpha2\alpha1$, and $\alpha10\alpha1$ are receptors for cartilage-specific type II collagen, there is great interest in determining whether they mediate differential responses of chondrocytes to changes in the ECM resulting from normal loading or pathologic changes. The $\alpha5\alpha1$ integrin is the prominent integrin in human adult articular cartilage. Depending on the method of analysis, adult chondrocytes also express $\alpha1\alpha1$ and $\alpha v\alpha5$ integrins accompanied by weaker expression of $\alpha3\alpha1$ and $\alpha v\alpha3$. Normal adult articular chondrocytes express little or no $\alpha2\alpha1$, whereas expression of $\alpha2\alpha1$ and $\alpha3\alpha1$ integrins is associated with a

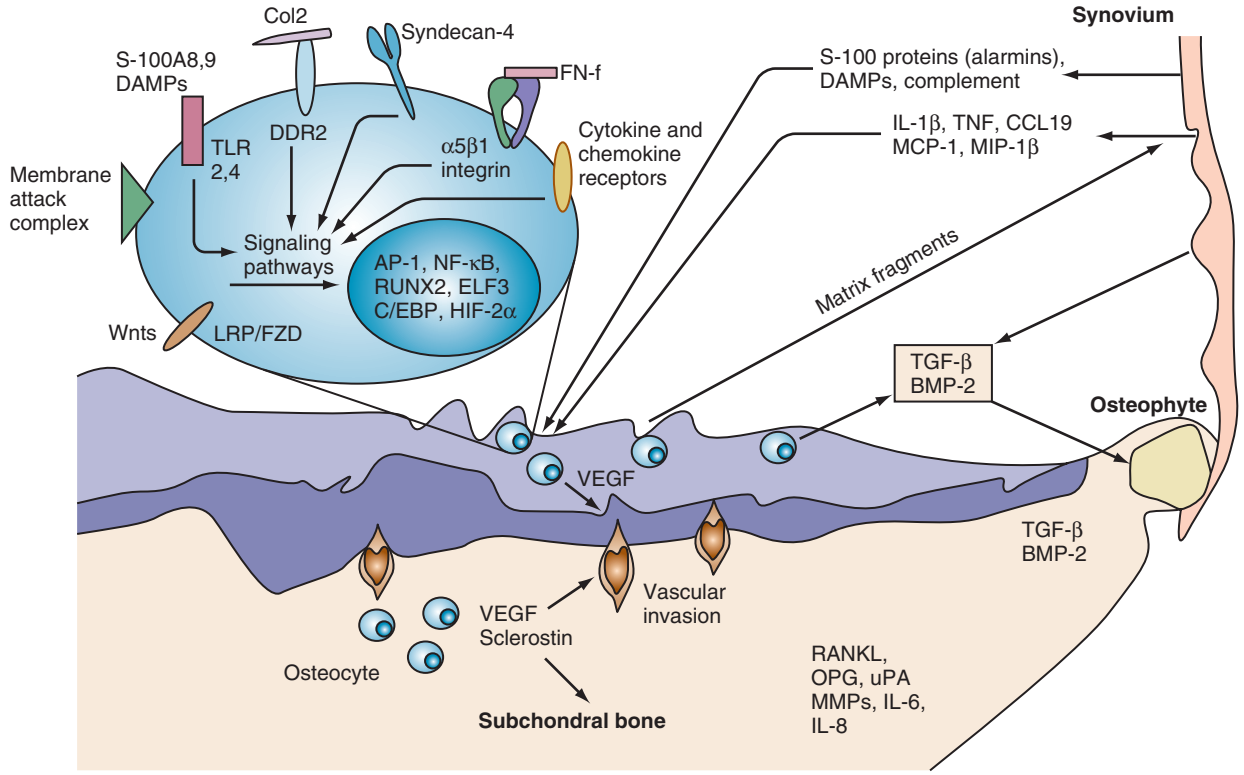

**Figure 3-5** Selected factors involved in the osteoarthritic process in the synovium, cartilage, and bone. Proteins including S-100 proteins (alarmins) and damage-associated molecular pattern molecules (DAMPs), cytokines (interleukin [IL]-1β, tumor necrosis factor [TNF], and IL-15), chemokines (C-C motif ligand19 [CCL19], monocyte chemotactic protein-1 [MCP-1], and macrophage inhibitory protein [MIP-1β]), and complement components released from the synovium can stimulate articular chondrocytes through activation of various cell surface receptors, including Toll-like receptors (TLRs) and cytokine and chemokine receptors, or by formation of the complement membrane attack complex. Other factors that activate cartilage matrix destruction include binding of native type II collagen to discoidin domain receptor 2 (DDR2); fibronectin fragments to the α5β1 integrin; wingless type (Wnt) proteins to LRP/frizzled (FZD) complexes; and extra-cellular ligands to the heparin sulfate proteoglycan syndecan-4. Syndecan-4 may also act by targeting A Disintegrin and Metalloproteinase with Thrombospondin Motifs-5 (ADAMTS-5) to the cell surface. Various signaling pathways lead to activation of a set of transcription factors that translocate to the nucleus and regulate expression of matrix-degrading enzymes and inflammatory mediators. Matrix fragments released from the cartilage can stimulate further synovitis. Production of vascular endothelial growth factor (VEGF) in cartilage and bone stimulates vascular invasion from subchondral bone into the zone of calcified cartilage. VEGF, sclerostin, receptor activator of nuclear factor-κB (NF-κB) ligand (RANKL), osteoprotegerin (OPG), urokinase-type plasminogen activator (uPA), matrix metalloproteinase (MMP)s, IL-6, and IL-8 mediate bone remodeling and potentially diffuse to the cartilage to also promote cartilage matrix destruction. Transforming growth factor (TGF)-β and bone morphogenic protein (BMP)-2 produced in the synovium, cartilage, and bone stimulate osteophyte formation. AP-1, Activator protein 1; C/EBP, CCAAT enhancer binding protein; HIF, hypoxia-inducible factor. *(Modified from Loeser RF, Goldring SR, Scanzello CR, Goldring MB: Osteoarthritis: a disease of the joint as an organ.* Arthritis Rheum *64:1697–1707, 2012.)*

proliferative phenotype, as in fetal chondrocytes and in chondrosarcoma and chondrocyte cell lines. In growth plate chondrocytes, α5α1, αvα5, and α10α1 are important for joint formation, chondrocyte proliferation, hypertrophy, and survival. Knockout of α1 integrin results in severe growth plate abnormalities and chondrodysplasias, whereas α1 integrin knockout mice develop OA without growth plate abnormalities. Importantly, α10α1 is the critical collagen receptor in skeletal development.[50]

Cellular binding to immobilized ECM proteins or integrin receptor aggregation with activating antibodies can promote numerous intra-cellular signaling events.[49] As in other cell types, integrin signaling is mediated by interaction with intra-cellular protein tyrosine kinases, such as pp125 focal adhesion kinase (FAK) and pyk2Pyk2, which interact with the integrin cytoplasmic tail and induce a conformational change in the receptor subunits. Changes in organization of the cytoskeleton are associated with the formation of integrin signaling complexes, which contain scaffolding proteins such as talin, paxillin, and α-actinin, in addition to FAK and the integrin-linked kinase (ILK). Mice lacking ILK in cartilage display chondrodysplasia, a phenotype similar to that of cartilage-specific β1 integrin knockout mice.

Cooperative signaling among integrins and growth factors is a fundamental mechanism in the regulation of cellular functions.[49] Integrin aggregation and receptor occupancy enhance phosphorylation of growth factor receptors and activation of mitogen-activated protein kinases (MAPKs), notably extra-cellular signal-regulated kinase (ERK)-1 or ERK-2.[51] Integrins mediate the effects of mechanical forces through activation of cell signaling, a process termed *mechanotransduction*.[52]

Normal chondrocytes use α5β1 as a mechanoreceptor. As the primary fibronectin receptor, α5β1 plays a role in cartilage degradation by binding to fibronectin fragments that upregulate matrix metalloproteinases (MMPs), such as MMP-3 and MMP-13. Chondrocyte adhesion to

fibronectin or binding to fibronectin fragments also increases the production of cytokines and other catabolic or inflammatory mediators through a mechanism requiring reactive oxygen species (ROS). The specificity of these responses depends on the relative expression of α-integrin subunits on the chondrocyte cell surface.

### Other Cell Surface Receptors in Chondrocytes

Other integral membrane proteins found in chondrocytes include cell determinant 44 (CD44), annexins, syndecans, and discoidin domain receptor 2 (DDR2). CD44, a receptor for hyaluronan, binds collagen and fibronectin. Through specific interactions with hyaluronan, CD44 has a role in the assembly, organization, and maintenance of the chondrocyte pericellular matrix. CD44 expression is upregulated in chondrocytes in articular cartilage from patients with RA and in experimental OA. Chondroprotective agents and anabolic factors may ameliorate cartilage matrix destruction by reducing CD44 fragmentation that disrupts hyaluronan-CD44 interactions and has adverse effects on the pericellular matrix.[53,54]

Annexin V, also known as *annexin CII*, is a 34 kDa integral membrane protein that binds type II collagen and shares extensive homology with the calcium-binding proteins calpactin and lipocortin. Annexins II, V, and VI have been detected in chondrocytes, where they likely play roles in physiologic mineralization of skeletal tissues and in pathologic mineralization of articular cartilage. Annexin V was first detected in chick cartilage and was described as a type II collagen–binding protein that anchors chondrocytes to the ECM. In growth plate chondrocytes, annexins are required for calcium ion uptake and subsequent mineralization.[55] Annexin A6 is highly expressed in OA cartilage and plays a role in catabolic signaling.[56]

Syndecans have important roles during cartilage development and homeostasis. Syndecans link to the cell surface via glycosyl phosphatidylinositol and bind growth factors, proteinases and inhibitors, and matrix molecules through heparan sulfate side chains on the extra-cellular domain.[57] Syndecan-1, syndecan-3, and syndecan-4 are upregulated in OA cartilage. Syndecan-4 is a positive effector of aggrecan activity through controlling the synthesis of the stromelysin, MMP-3.

In contrast to integrins, which bind collagen fragments, DDR2 binds specifically to type II and X collagen fibrils, leading to activation of its integral receptor tyrosine kinase. DDR2 is upregulated in OA cartilage and induces specifically the expression of MMP-13 associated with cleavage of type II collagen. The serine proteinase, high temperature requirement A1 (HTRA1), which is induced by TGF-β and increased in OA articular cartilage, is responsible for disrupting the pericellular matrix, thereby exposing DDR2 to activation by fibrillar type II collagen.[58,59]

## ANGIOGENIC AND ANTIANGIOGENIC FACTORS

Adult articular cartilage is among the few avascular tissues in mammalian organisms; this property and the presence of angiogenesis inhibitors make it resistant to vascular angiogenesis and invasion by inflammatory and neoplastic cells. Troponin I, MMP inhibitors, chondromodulin-I, and endostatin, a 20 kDa proteolytic fragment of type XVIII collagen, all function as endogenous angiogenic inhibitors in cartilage. In conditions in which extensive remodeling of ECM occurs, as in arthritis, the cartilage becomes susceptible to invasion by vascular endothelial and mesenchymal cells from the synovium and subchondral bone.[60] VEGF, which is an essential mediator of angiogenesis during endochondral ossification, is induced by inflammatory cytokines, hypoxia, and mechanical overload.[38,51] In OA, in which abnormal biomechanics and joint effusions cause severe hypoxia, chondrocytes may produce VEGF, inducing angiogenesis at the chondro-osseous junction and contributing to expansion of the calcified cartilage, tidemark duplication, and cartilage thinning.[61] TGF-β–mediated angiogenesis in the subchondral bone may be among the earliest events driving OA,[62] where microcracks produced by mechanical stress and exacerbation of naturally occurring pores provide conduits for vascular invasion into the calcified cartilage and diffusion of small molecules.[63] In RA, ingrowth of blood vessels and synovial pannus into cartilage contributes to degradation of the cartilage matrix. Gene expression profiling analyses comparing inflamed and noninflamed areas of synovium from the same patients with OA identified *STC1*, encoding stanniocalcin-1, a molecule that plays roles in angiogenic sprouting via the VEGF/VEGF receptor 2 pathway, as the most highly upregulated gene in inflamed synovial membrane.[64] Articular cartilage is aneural, and the sensory nerve fibers observed in the vascular channels that are associated with osteochondral angiogenesis may constitute a potential source of symptomatic pain.[65] The clinical importance of these observations is supported by the report that VEGF blockade with bevacizumab inhibits post-traumatic OA in a rabbit model with pain relief associated with prevention of both synovitis and angiogenesis.[66]

## ROLES OF GROWTH AND DIFFERENTIATION (ANABOLIC) FACTORS IN NORMAL CARTILAGE METABOLISM

Growth and differentiation factors generally are considered positive regulators of homeostasis of mature articular cartilage because of their capacity to stimulate chondrocyte anabolic activity and, in some cases, inhibit catabolic activity.[41,67] The best-characterized anabolic factors in the context of their production and action in articular cartilage include insulin-like growth factor (IGF)-I and members of the FGF and TGF-β/BMP families. The PTHrP, Ihh, and Wnt/β-catenin pathways have been implicated in maintenance of cartilage homeostasis or OA disease processes. Many of these factors also regulate chondrogenesis and endochondral ossification during skeletal development.[28,33,35] In adult cartilage, their expression declines with age—a risk factor for OA—and their activities are downregulated.[67]

### Insulin-like Growth Factor

IGF-I was first described as *somatomedin C*, a serum factor controlling sulfate incorporation by articular cartilage in vitro, and it was later found to have the specific capacity to stimulate or maintain chondrocyte phenotype in vitro

by promoting the synthesis of type II collagen and aggrecan. IGF-I is a competence factor for cell proliferation that is categorized more appropriately as a differentiation factor because its limited mitogenic activity seems to depend on the presence of other growth factors, such as FGF-2, a progression factor. IGF-I is considered an essential mediator of cartilage homeostasis through its capacity to stimulate proteoglycan synthesis, promote chondrocyte survival, and oppose the activities of catabolic cytokines in cooperation with other anabolic factors such as BMP-7. IGF-I and insulin can activate cell signaling via the IGF-I tyrosine kinase receptor or the type I insulin receptor at concentrations proportional to their binding affinities.[67]

Specific IGF-binding proteins (IGF-BPs) that do not recognize insulin also regulate IGF-I activity. Chondrocytes at different stages of differentiation express IGF-I and IGF receptors and different arrays of IGF-BPs, providing a unique system by which IGF-I can exert different regulatory effects on these cells. IGF-BP-2 is a positive regulator that increases proteoglycan synthesis in chondrocytes, whereas binding of IGF-BP-3 to IGF-I negatively regulates the anabolic functions of IGF-I. IGF-BP-3 may also directly inhibit chondrocyte proliferation in an IGF-independent manner.

In OA cartilage, the normal anabolic function of IGF-I may be disrupted because chondrocytes from animals with experimental arthritis and from patients with OA are hyporesponsive to IGF-I, despite normal or increased IGF-I receptor levels. This hyporesponsiveness has been attributed to increased levels of IGF-BPs that may interfere with IGF-I actions and overproduction of nitric oxide through disruption of integrin signaling, reduction of phosphorylation of the IGF-I receptor, stimulation of cyclic guanosine monophosphate production, or suppression of mitochondrial oxidative metabolism. IGF-I can oppose the effects of inflammatory cytokines that promote cartilage degradation and inhibit proteoglycan synthesis.

## Fibroblast Growth Factor

Members of the FGF family, including FGF-2, FGF-4, FGF-8, FGF-9, FGF-10, and FGF-18, together with the FGF receptors, FGFR1, FGFR2, FGFR3, and FGFR4, coordinate patterning and cell proliferation during chondrogenesis and endochondral ossification in embryonic and postnatal growth plates.[33] The most extensively studied is FGF-2, or basic FGF, which is a potent mitogen for adult articular chondrocytes, but findings regarding its effects on the synthesis of cartilage matrix are contradictory, showing stimulation, inhibition, or no effect on proteoglycan synthesis.

The FGFs are generally considered homeostatic factors in joint tissues.[68,69] FGF-2 stored in the adult cartilage matrix is released with mechanical injury or with loading, suggesting a mechanism for modulating chondrocyte proliferation and anabolic activity. Different FGF receptors in cartilage may mediate opposing effects: FGF-2 promotes cartilage protection via FGFR3 and cartilage destruction via FGFR1.[70] Of the four receptors, FGFR1 and FGFR3 are the most abundant, and the ratio of FGFR3 to FGFR1 is reduced in OA cartilage. Furthermore, cartilage-specific deletion of the *Fgfr1* gene attenuates articular cartilage degeneration in mice.[71]

In cartilage development, FGF-18 negatively regulates chondrocyte proliferation and terminal differentiation in the growth plate via FGFR3. In articular cartilage, FGF-18 has a role in the maintenance of homeostasis via FGFR3 and protects against loading-induced damage in cartilage explants ex vivo.[72] In vivo, intra-articular administration of FGF-18 protects against cartilage damage in a rat model of injury-induced arthritis.[73] Thus there is considerable interest in the potential of anabolic factors such as FGF-18 for enhancing cartilage regeneration with tissue engineering approaches.[74] A recent proof-of-concept trial with human recombinant FGF-18, sprifermin, showed statistically significant dose-dependent improvement in prespecified secondary structural endpoints by magnetic resonance imaging (MRI), radiographic joint space narrowing, and Western Ontario and McMaster Universities Arthritis Index (WOMAC) pain scores.[75]

## TGF-β/BMP Superfamily

Activities of the TGF-β/BMP superfamily in the skeleton were first discovered by Marshall Urist as constituents of demineralized bone that induced new bone formation when implanted into extraskeletal sites in rodents. These bioactive morphogens subsequently were extracted, purified, and cloned and were found to regulate the early commitment of mesenchymal cells to chondrogenic and osteogenic lineages during cartilage development and endochondral bone formation (Table 3-2). The TGF-β/BMP superfamily includes activins, inhibins, müllerian duct inhibitory substance, nodal, glial-derived neurotrophic factor, osteogenic protein-1 (OP-1) (or BMP-7), and growth differentiation

**TABLE 3-2** Bone Morphogenetic Protein Superfamily

| BMP | Other Names | Potential Function |
|---|---|---|
| BMP-2 | BMP-2A | Cartilage and bone morphogenesis |
| BMP-3 | Osteogenin, GDF-10 | Bone formation |
| BMP-4 | BMP-2B | Cartilage and bone morphogenesis |
| BMP-5 | | Bone morphogenesis |
| BMP-6 | Vgr-1 | Cartilage hypertrophy |
| BMP-7 | OP-1 | Cartilage and bone morphogenesis |
| BMP-8 | OP-2 | Bone morphogenesis |
| BMP-9 | GDF-2 | Cartilage morphogenesis |
| BMP-10 | | Unknown |
| BMP-11 | GDF-11 | Unknown |
| BMP-12 | GDF-7, CDMP-3 | Cartilage morphogenesis |
| BMP-13 | GDF-6, CDMP-2 | Cartilage morphogenesis |
| BMP-14 | GDF-5, CDMP-1 | Cartilage morphogenesis |

BMP, Bone morphogenetic protein; CDMP, cartilage-derived morphogenetic protein; GDF, growth and differentiation factor; OP, osteogenic protein; Vgr-1, vegetal-related-1.

factors (GDFs), also called *cartilage-derived morphogenetic proteins* (CDMPs). In addition to regulating cartilage condensation and chondrocyte differentiation, members of this superfamily play key roles in site specification and cavitation of synovial joints (see Chapter 1) and in the development of other organ systems. Many of these factors, including BMP-2, -6, -7, -9, TGF-β, and CDMP-1, are able to induce chondrogenic differentiation of mesenchymal progenitor cells in vitro. They also may have direct effects on mature articular chondrocytes in vivo and in vitro and are important for cartilage maintenance.[34]

### Transforming Growth Factor-β

TGF-β was so named because it was discovered that it could transform cells to grow in soft agar. TGF-β is not a potent inducer of chondrocyte proliferation, however; rather, it controls early mesenchymal cell condensation, as well as chondrocyte differentiation at early and late stages of chondrogenesis and endochondral ossification. Both inhibition and stimulation of the synthesis of aggrecan and type II collagen by TGF-β have been observed in vitro. However, TGF-β by itself cannot rescue the type II collagen phenotype when cells have undergone dedifferentiation during serial passaging. Levels of TGF-β measured in synovial fluids of persons with OA and RA may reflect anabolic processes in cartilage and other joint tissues. TGF-β may promote anabolism by inducing the expression of tissue inhibitors of MMP (TIMPs).

TGF-β1, TGF-β2, and TGF-β3 generally are considered to be potent stimulators of proteoglycan and type II collagen synthesis in primary chondrocytes and cartilage explants in vitro. However, TGF-β signaling can play both protective and deleterious roles in OA.[76] Although intra-articular injection of TGF-β stimulates proteoglycan synthesis and limits cartilage damage in inflammatory arthritis models, injection or adenovirus-mediated delivery of TGF-β1 may result in adverse effects in joint tissues, such as osteophyte formation, swelling, and synovial hyperplasia. Administration of agents that block TGF-β activity, such as the soluble form of TGF-βRII, inhibitory SMADs, or the physiologic antagonist, latency-associated peptide-1, increases proteoglycan loss and cartilage damage in experimental models of OA.

Recent studies have also identified aberrant TGF-β signaling in bone as a key pathway in OA.[77] In the anterior cruciate ligament (ACL) transection model of OA, high doses of a TGF-β inhibitor administered systemically promoted cartilage proteoglycan loss, whereas lower doses prevented the migration and/or localization of mesenchymal stem cells (MSCs), osteoprogenitors, and osteoblasts in the subchondral bone of operated limbs and attenuated neovascularization and cartilage loss.[62] Transgenic expression of active TGF-β in osteoblasts induced the formation of nestin-positive MSCs in clusters, whereas knockout of *Tgfbr2* in nestin-positive MSCs prevented MSC migration to the subchondral bone and normalized bone parameters, cartilage homeostasis, and limb function. Furthermore, implantation of a TGF-β–specific antibody in the subchondral bone attenuated the OA changes in both the cartilage and bone, suggesting that bone-targeted therapies may be useful in some forms of the disease.[62]

### Bone Morphogenetic Proteins

BMPs constitute a large subclass of the TGF-β superfamily essential for normal appendicular skeletal and joint development.[78] The isolation and cloning of the first BMP family members from bone prompted a search for cartilage-derived BMPs, or CDMPs—CDMP-1, -2, and -3—which are classified as GDF-5, -6, and -7. The BMPs may be divided into four distinct subfamilies based on the similarity of primary amino acid sequences:

1. BMP-2 and -2B (BMP-4), which are 92% identical in the 7-cysteine region
2. BMP-3 (osteogenin) and -3B (GDF-10)
3. BMP-5, -6, -7 (OP-1), BMP-8 (OP-2), BMP-9 (GDF-2), BMP-10, and BMP-11 (GDF-11)
4. BMP-12 (GDF-7 or CDMP-3), BMP-13 (GDF-6 or CDMP-2), BMP-14 (GDF-5 or CDMP-1), and BMP-15.

BMP-1 is not a member of this family but is an astacin-related MMP that cleaves the BMP inhibitor chordin and acts as a procollagen C-proteinase.

Several BMPs, including BMP-2, -7 (OP-1), and GDF-5/CDMP-1, can stimulate differentiation of mesenchymal precursors into chondrocytes and promote the differentiation of hypertrophic chondrocytes. BMP-2, -4, -6, -7, -9, and -13 can enhance the synthesis of type II collagen and aggrecan by articular chondrocytes in vitro. BMP-2 also is expressed in normal and OA articular cartilage, and it is a molecular marker, along with type II collagen and FGFR3, for the capacity of adult articular chondrocyte cultures to form stable cartilage in vivo. BMP-7 is expressed in mature articular cartilage and is possibly the strongest anabolic stimulus for adult chondrocytes in vitro because it increases aggrecan and type II collagen synthesis more strongly than IGF-I. In addition, BMP-7 reverses many of the catabolic responses induced by IL-1β, including induction of MMP-1 and -13, downregulation of TIMP, and downregulation of proteoglycan synthesis in primary human articular chondrocytes. CDMP-2 is found in articular cartilage, skeletal muscle, placenta, and hypertrophic chondrocytes of the epiphyseal growth plate. CDMP-1 and -2 maintain the synthesis of type II collagen and aggrecan in mature articular chondrocytes, although they are less effective initiators of chondrogenesis than other BMPs in early progenitor cell populations in vitro.

BMPs have pleiotropic effects in vivo, however, acting in a concentration-dependent manner. While initiating chondrogenesis in the limb bud, they generally set the stage for bone morphogenesis. Several BMPs also are true morphogens for other tissues, such as kidney, eye, heart, and skin.

## Receptors, Signaling Molecules, and Antagonists that Mediate Chondrocyte Responses to Growth and Differentiation Factors

Major pathways activated by the growth and differentiation factors previously discussed involve members of the ERK1/2, p38 MAPK, and phosphatidylinositol 3′-kinase (PI3K)/v-akt murine thymoma viral oncogene homolog (AKT) pathways.[79] As in other cell types, FGF family members

activate kinases of the ERK1/2 and p38 MAPK cascades in chondrocytes. Specific inhibitors of these pathways block FGF-2–induced and FGF-18–induced mitogenesis in chondrocytes and prevent FGF-2 induction of Sox9 in primary chondrocytes. The PI3K pathway is required for the stimulation of proteoglycan synthesis by IGF-I in primary human articular chondrocytes, whereas the ERK1/2 pathway acts as a negative regulator.[67]

TGF-β and BMP family members transduce signals through the formation of heteromeric complexes of ligand-specific receptors, which have serine-threonine kinase activity. The specificity of subsequent signals is determined mainly by the type I receptors. Type I and type II receptors are required for signal transduction. Seven types of type I receptors, called *activin receptor–like kinases* (ALKs), have been identified in mammals and have similar structures. TGF-β interacts with TGFβRII, which recruits a TGF-β type I receptor (principally TGFβRI) to form a heterotrimeric receptor complex. The constitutively active TGFβRII kinase phosphorylates TGFβRI at serine and threonine residues. Three type I receptors, type IA BMP (BMPR-IA or ALK-3), BMPR-IB (ALK-6), and ALK-2, mediate BMP signaling. Although BMPR-1 receptors are able to bind ligand in the absence of type II BMP receptors, cooperativity has been shown in binding assays. On ligand binding, analogous to TGFβRI and TGFβRII, type I BMP receptors are phosphorylated by the type II BMP receptors, which include activin (Act)RII, ActRIIB, and ALK. Spatial and temporal differences in the distribution of these receptors in different tissues can govern the response patterns to different members of the TGF-β/BMP family.

The canonical SMAD pathway mediates TGF-β and BMP signaling through phosphorylation of receptor-activated SMADs (R-SMADs), which are related to the *Drosophila* mothers against decapentaplegic (MAD) and nematode SMA signaling molecules. TGFβRI receptors (ALK-4, -5, and -7) phosphorylate Smad2 and Smad3 transcription factors. BMPs act primarily through ALK-1, -2, -3, and -6 to activate Smad1, Smad5, and Smad8 and generally promote chondrocyte hypertrophic differentiation. The R-SMADs form complexes with the common Smad4 and translocate to the nucleus, where they bind to SMAD-specific DNA binding sites in the promoters of target genes.

The major route of TGF-β signaling in healthy articular cartilage is through canonical ALK-5, which activates Smad2/3 to inhibit chondrocyte hypertrophy, but when TGF-β interacts with ALK-1, it signals through Smad1/5/8 and induces MMP-13 and other degradative enzymes[76] and nerve growth factor (NGF).[80] Increase of the ALK-1/ALK-5 ratio during aging[76] may account for the aberrant chondrocyte responses associated with the development of OA and off-target effects of TGF-β injections in joints that result in osteophyte formation and synovial fibrosis.

Further regulation is provided by inhibitory SMADs, including Smad6 and Smurf1 and Smurf2, which primarily inhibit Smad1/5/8 signaling by accelerating the proteosomal breakdown of phosphorylated Smads. The aberrant hypertrophic differentiation in Smad3-deficient mice can be rescued by restoring TGF-β–activated kinase 1 (TAK1) and activating transcription factor (ATF)-2 signaling,[81] but inhibition of TAK1 or Janus kinase (JAK) can rescue impaired differentiation of MSCs in OA.[82]

BMP antagonists play important roles in spatial and temporal regulation of BMP activities during skeletal development. Originally discovered in *Xenopus*, they act as antagonists by determining the bioavailability of BMPs for binding to BMP receptors.[83] The roles of noggin and chordin seem to be crucial for determining boundaries during joint morphogenesis. They display different spatial and temporal patterns of expression, binding affinities, and susceptibility to proteinases that release BMP. BMPs bind to chordin and noggin via cysteine-rich domains that are similar to domains in the N-terminal propeptides of fibrillar procollagens I, II, III, and V, which also bind BMPs and are susceptible to cleavage by MMPs. BMP may be released from chordin by cleavage with MMPs or BMP-1/tolloid, whereas noggin binds BMP with high affinity and cannot be cleaved to release BMP.

Follistatin, gremlin, chordin, and chordin-like 2 are upregulated in OA cartilage. Follistatin, which has been linked to inflammatory processes; gremlin, which is associated with hypertrophic phenotype; and chordin appear at different stages of OA and with different topographic distribution. Because each antagonist binds preferentially to different BMPs, the differential expression may serve as a feedback mechanism to balance anabolic activities at different stages.

The Wnt/β-catenin pathway plays a role in both cartilage and bone development and disease.[84] The cellular responses are governed by the availability of Wnt ligands in different tissues and their use of distinct, canonical versus noncanonical, pathways over the course of differentiation and during disease.[84] The Wnt antagonists, including sclerostin (SOST), originally described as osteocyte-specific, dickkopf-related protein-1 (DKK1), and secreted frizzled-related protein 1 (sFRP1), have been explored as regulators and biomarkers of articular cartilage homeostasis, because they may decrease hypertrophic conversion and expression of proteinases in vitro and, in some cases, in vivo.[85-88]

## ROLE OF THE CHONDROCYTE IN CARTILAGE DISEASE

The chondrocyte, the unique cell type in mature cartilage, maintains a stable equilibrium between the synthesis and the degradation of matrix components. During aging and in the presence of joint diseases, such as RA and OA, this equilibrium is disrupted, and the rate of loss of collagens and proteoglycans from the matrix exceeds the rate of deposition of newly synthesized molecules. Cartilage destruction in OA is believed to be chondrocyte mediated in response to biomechanical insult and may occur directly or indirectly through the production of cytokines and cartilage matrix–degrading proteinases in cartilage and other joint tissues[89] (Figure 3-6).

Cartilage destruction in RA occurs primarily in areas contiguous with the proliferating synovial pannus as a result of the release and activation of proteinases from the synovial cells and, to some extent, at the cartilage surface, which is exposed to matrix-degrading enzymes from polymorphonuclear neutrophils in the synovial fluids. In addition to the direct action of proteinases, RA synovial tissues contribute indirectly to cartilage loss by releasing cytokines and other mediators that act on the chondrocytes to

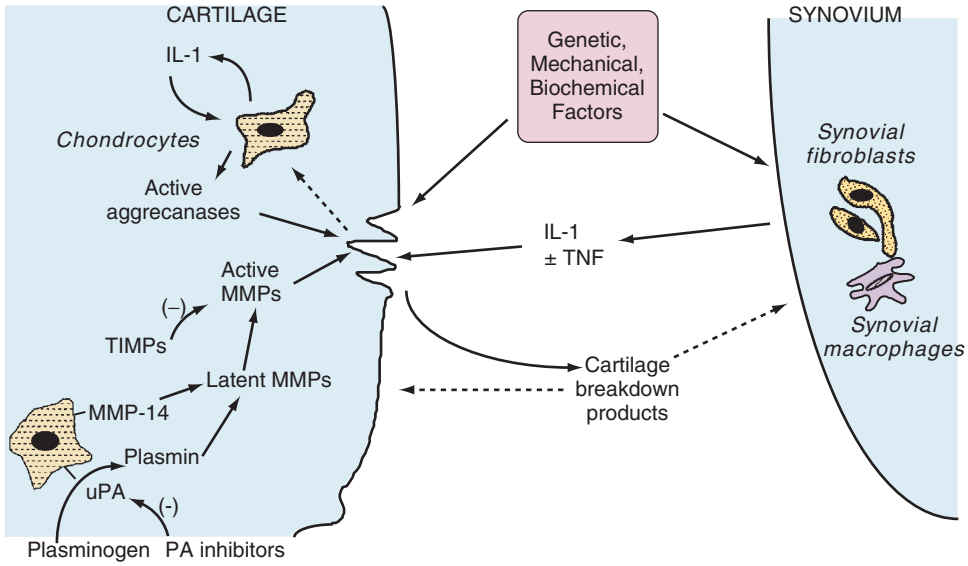

**Figure 3-6** The role of chondrocyte-derived proteinases in cartilage destruction in osteoarthritis. Although studies in vitro and in vivo have shown that the chondrocyte can respond directly to mechanical loading, to catabolic cytokines such as interleukin (IL)-1 and tumor necrosis factor (TNF), and to cartilage breakdown products, the initiating signals and their relative importance have not been defined clearly. MMP, Matrix metalloproteinase; TIMP, tissue inhibitor of metalloproteinase; uPA, urinary plasminogen activator. *(Modified from Goldring MB: Osteoarthritis and cartilage: the role of cytokines.* Curr Rheumatol Rep *2:459–465, 2000.)*

produce dysregulation of chondrocyte function. Understanding of basic cellular mechanisms regulating chondrocyte responses to inflammatory cytokines has been inferred from numerous studies in vitro using cultures of cartilage fragments or isolated chondrocytes and is supported by studies in experimental models of inflammatory arthritis, such as collagen-induced arthritis and antigen-induced arthritis in mice.[90-92]

Direct analysis of cartilage or chondrocytes from patients with OA undergoing joint replacement has yielded more information than is available from patients with RA, in whom cartilage damage is extensive. These studies indicate that chondrocytes produce not only pro-inflammatory cytokines but also inhibitory and anabolic cytokines that modulate responses. The impact of cytokines on chondrocyte function, particularly with respect to their various roles in cartilage destruction, has been reviewed extensively.[1,2,48] Studies of cartilage degradation in genetically modified mouse strains that are resistant to or accelerate the development of OA spontaneously with aging or when subjected to excessive biomechanical injury have yielded information about the molecular effectors of the disease and potential targets for therapy.[90,93-95]

## Cartilage Matrix–Degrading Proteinases

Chondrocytes synthesize and secrete MMPs in latent forms, which are activated outside the cells via activation cascades. An important cascade in cartilage is initiated by plasmin, the product of plasminogen activator activity, which may be produced by the chondrocyte; plasmin activates latent stromelysin (MMP-3), an activator of latent collagenases. In early studies, chondrocytes were among the first identified sources of TIMP-1, and they are now known to synthesize additional TIMPs, including TIMP-3, which is the major inhibitor of aggrecanase activities. TIMPs and MMPs detected in synovial fluids reflect the adaptive response to the local imbalance caused by increased production of active MMPs by chondrocytes and other joint tissues. Collagenases 1, 2, and 3 (MMP-1, -8, and -13); gelatinases (MMP-2 and -9); stromelysin-1 (MMP-3); membrane type 1 (MT1)-MMP (MMP-14); and the aggrecanases, a disintegrin and metalloproteinase with thrombospondin motifs (ADAMTS)-4 and ADAMTS-5, specifically degrade native collagens and proteoglycans in cartilage matrix (Table 3-3).[96,97]

MMPs, aggrecanases, and the cleavage fragments generated by them are localized in regions of cartilage degradation and are detected in synovial fluids and cartilage of persons with either OA or RA.[1,2] Expression of MMP-13 in OA and RA cartilage and its ability to degrade type II collagen more effectively suggest a major role for this enzyme in cartilage degradation. Postnatal overexpression of constitutively active MMP-13 in cartilage in mice produces OA-like changes in knee joints, and knockout of the gene encoding MMP-13 protects cartilage against surgically induced OA.[98] Deficiency of DDR2, a collagen receptor whose activation is associated with upregulation of MMP-13, attenuates development of OA induced by destabilization of the medial meniscus (DMM) surgery.[58] Deficiencies of the Runx2 and HIF-2α transcription factors that are key regulators of MMP-13 also protect against OA development or progression.[40] Nuclear factor-κB (NF-κB) transcription factors in response to their upstream activating kinases can directly modulate the amplitude of MMP-13 expression under inflammatory, mechanical, and oxidative stress.[99]

Although elevated levels of MMPs in RA synovial fluids likely originate from the synovium, intrinsic chondrocyte-derived chondrolytic activity is present at the cartilage-pannus junction and in deeper zones of cartilage matrix in

**TABLE 3-3** Chondrocyte Proteinases that Mediate Degradation of Cartilage Matrix

| Proteinase Class | Cartilage Matrix Substrates | Activity |
|---|---|---|
| **Matrix Metalloproteinases** | | |

some RA specimens. MMP-1 is expressed at lower levels than MMP-3 and MMP-13 in the RA synovial pannus but is also produced by chondrocytes. MMP-10, similar to MMP-3, activates procollagenases and is produced by the synovium and chondrocytes in response to inflammatory cytokines. MT1-MMP (MMP-14), produced principally by the synovial tissue, is important for synovial invasiveness and may also serve as an activator of other MMPs produced by chondrocytes.[96]

Several of the MMPs, including MMP-3, -8, -14, -19, and -20, are capable of degrading proteoglycans. Members of the reprolysin-related proteinases of the ADAM family, particularly ADAMTS-4 and ADAMTS-5, are now regarded as the principal mediators of aggrecan degradation.[100,101] The activities of MMPs and aggrecanases are complementary, however. Of the aggrecanases, ADAMTS-5 is associated with increased susceptibility to OA, as shown in *Adamts5*-deficient mice. TIMP-3, but not TIMP-1, -2, or -4, is a potent inhibitor of ADAMTS-4 and -5 in vitro, and TIMP-3 deficiency results in mild cartilage degradation similar to that seen in persons with OA.[102]

Cysteine proteinases, cathepsins B, K, S, and L, and the aspartic proteinase, cathepsin D, are lysosomal enzymes that may play a secondary role in cartilage degradation via intracellular digestion of products released by other proteinases.[103] Cathepsin B also may have a role in extra-cellular degradation of collagen telopeptides, collagens IX and XI, and aggrecan. Cathepsin K is expressed in synovial fibroblasts on the cartilage surface at the pannus-cartilage junction and is upregulated by inflammatory cytokines. Among the known cathepsins, cathepsin K is the only proteinase that is capable of hydrolyzing type I and type II collagens at multiple sites within the triple-helical regions, and its requirement for acidic pH may be provided by the microenvironment between the synovial pannus and the cartilage.[97]

Other MMPs, including MMP-16 and MMP-28, and ADAM family members, including ADAM-17/TNF converting enzyme (TACE), are expressed by chondrocytes, but their roles in adult cartilage have yet to be defined.[104,105] Identification of the precise roles of these proteinases and their endogenous inhibitors in chondrocyte-mediated cartilage degradation has provided the opportunity to develop targeted therapies that interfere with the activities of aggrecanases or MMPs without disrupting normal physiology.[106,107] MicroRNAs are of current interest as novel endogenous regulators targeting proteinases in cartilage, and epigenetic changes involving DNA methylation and

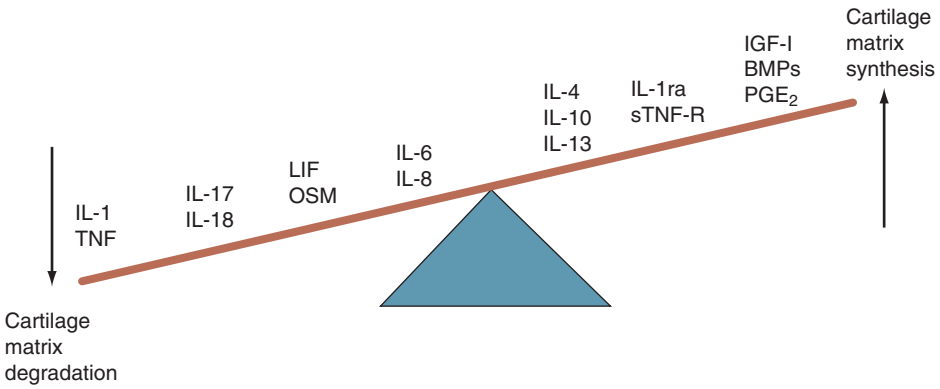

**Figure 3-7** The cytokine balance in cartilage metabolism. Soluble mediators toward the left of the balance promote the loss of cartilage matrix. Mediators on the right side prevent the synthesis or actions of catabolic cytokines and prevent loss of cartilage matrix. Anabolic factors, including insulin-like growth factor (IGF)-I and bone morphogenetic proteins (BMPs), along with prostaglandin $E_2$ ($PGE_2$), maintain or promote cartilage matrix synthesis. IL-1, Interleukin-1; IL-1ra, IL-1 receptor antagonist; LIF, lymphocyte-activating factor; OSM, oncostatin M; sTNF-R, soluble tumor necrosis factor receptor; TNF, tumor necrosis factor. *(Modified from Goldring MB: Osteoarthritis and cartilage: the role of cytokines.* Curr Rheumatol Rep *2:459–465, 2000.)*

histone modifications that differentially affect gene expression in cartilage are of current interest.[108,109]

## Balance of Cytokines in Cartilage Destruction

The roles of cytokines in cartilage metabolism must be considered in the context of the entire joint.[48] Sources of cytokines in the joint include the synovial macrophages and infiltrating mononuclear cells in the synovium, as well as the chondrocytes themselves.[110] Of the cytokines that affect cartilage metabolism, most are pleiotropic factors that were identified originally as immunomodulators but were found to regulate cellular functions in cells of mesenchymal origin. IL-1 and TNF not only stimulate chondrocytes to synthesize cartilage matrix–degrading proteinases, they also regulate matrix protein synthesis and cell proliferation. Considerable redundancy and overlap in biologic activities exist among the individual cytokines, and they do not act alone, but rather in synergy or partnership with or in opposition to other cytokines via cytokine networks. In addition to IL-1 and TNF, other catabolic cytokines have been characterized, as have inhibitory or anabolic cytokines produced by the chondrocytes themselves or by other cells in joint tissues (Table 3-4). Investigations in vitro and in vivo have begun to sort out the complexities of the cytokine networks and to determine how the balance in normal homeostasis can be restored when it is disrupted (Figure 3-7). Studies of type II collagen–induced arthritis and other types of induced arthritis in transgenic animals with overexpressed or deleted genes encoding cytokines, their receptors, or activators have provided further insight into the roles of these factors in cartilage destruction.

### Interleukin-1 and Tumor Necrosis Factor

IL-1 and TNF are the predominant catabolic cytokines involved in the destruction of articular cartilage. Early work first identified IL-1 as a soluble factor, termed *catabolin*, in supernatants of normal, noninflamed porcine synovial fragment cultures that stimulated chondrocytes to degrade the surrounding cartilage matrix. Similar activities in culture supernatants from mononuclear cells and rheumatoid synovium were attributed to IL-1, and the catabolin isoforms were identified as IL-1α and IL-1β. Since those early findings, numerous studies in vitro and in vivo indicate that IL-1 and TNF, originating primarily from the inflamed synovium, are the predominant catabolic cytokines involved in the destruction of articular cartilage in RA.[111]

Major events in OA pathogenesis occur within the cartilage itself, and evidence suggests that chondrocytes participate in this destructive process not only by responding to cytokines released from other joint tissues but also by synthesizing them.[1,2] They may be exposed continuously to the autocrine and paracrine effects of IL-1 and other inflammatory mediators at high local concentrations. Chondrocytes in OA cartilage, especially those in clonal clusters, are positive for IL-1 immunostaining and express IL-1β converting enzyme (caspase-1) and type 1 IL-1 receptor (IL-1R1). IL-1 co-localizes with TNF, MMP-1, -3, -8, -13, and type II collagen cleavage epitopes in regions of matrix depletion in OA cartilage. The increased sensitivity of OA chondrocytes to IL-1 and TNF may be associated with increased levels of IL-1R1 and p55 TNF receptor at localized sites. These cytokines, MMPs, and type II collagen cleavage epitopes are observed in regions of matrix depletion in OA and RA cartilage in humans and in animal models.

The assumption has been that *IL1B* mRNA expressed in chondrocytes of OA cartilage could result in translation to pro-IL-1β and secretion of IL-1β. However, the inflammasome complex, consisting of NLRP3, ASC, and the IL-1β activator caspase-1, does not appear to be active in cartilage, thereby preventing secretion and autocrine activity of this cytokine. Furthermore, deficiency of genes encoding NLRP3 or IL-1β did not prevent catabolic responses induced by TNF, lipopolysaccharide, or mechanical load in cartilage explants from knockout mice.[112] These results suggest that locally produced IL-1β is not available to act in an autocrine or paracrine manner in cartilage, but rather this cytokine could be released from the synovium and other tissues to elicit chondrocyte responses.[112]

Originally known as *cachectin*, TNF produces many effects on chondrocytes in vitro that are similar to those of IL-1β, including stimulation of the production of matrix-degrading proteinases and suppression of cartilage matrix synthesis. Although IL-1β is 100-fold to 1000-fold more potent on a molar basis than TNF, strong synergistic effects occur at low concentrations of the two cytokines together, eliciting more severe cartilage damage than injection of either cytokine alone. The concept that TNF drives acute inflammation, whereas IL-1β has a pivotal role in sustaining inflammation and cartilage erosion, has been derived from work in animal models of RA using cytokine-specific neutralizing antibodies, soluble receptors, or receptor antagonists and in transgenic or knockout mouse models.

### Cytokine Networks

The cytokine networks that affect chondrocytes must also be considered within the context of the entire joint.[1,2,9,48] IL-1β and TNF can induce chondrocytes to produce other pro-inflammatory cytokines, including IL-6, leukemia inhibitory factor, IL-17, IL-18, and chemokines. IL-6 seems to play a dual role by increasing expression of IL-1ra, soluble TNF receptor, and TIMPs, while also enhancing immune cell function and inflammation. The activity of IL-6 requires soluble IL-6 receptor to synergize with IL-1 to stimulate expression of MMPs and ADAMTS and to downregulate *COL2A1* and aggrecan in cultured chondrocytes. IL-6 knockout mice are more susceptible to cartilage degeneration during aging, however, suggesting that this cytokine may play a protective role in normal physiology.

Other members of the IL-6 family that act via receptors that heterodimerize with gp130 also may serve modulatory roles. IL-11 shares several actions of IL-6, including stimulation of TIMP production, without affecting MMP production by chondrocytes, and it may inhibit cartilage destruction. Leukemia inhibitory factor (LIF) participates in a positive feedback loop by increasing the production of IL-6 by chondrocytes. Oncostatin M (OSM), a product of macrophages and activated T cells, is a potent stimulator of chondrocyte production of MMPs and aggrecanases in synergism with IL-1β or TNF.

IL-17 and IL-18 are potent catabolic factors that stimulate the production of IL-1β, MMPs, and other pro-inflammatory and catabolic factors in human chondrocytes. IL-17 is produced by activated T helper (Th) type 1, or $CD4^+$, lymphocytes and binds to a receptor that is not related to any known cytokine receptor family and can act in synergy with other cytokines. IL-17 can drive T cell–dependent erosive arthritis in TNF-deficient and IL-1ra knockout mice, and treatment of collagen-induced arthritis or antigen-induced arthritis mice with neutralizing IL-17 antibody effectively inhibits cartilage destruction in those models of RA. IL-18 is produced by macrophages, and its receptor shares homology with IL-1RI. IL-4, IL-10, IL-13, and the naturally occurring IL-1Ra are classified as inhibitory cytokines because they decrease the production and activities of catabolic and pro-inflammatory cytokines in chondrocytes in vitro and suppress cartilage destruction in vivo (see Table 3-4). IL-4 and IL-10 inhibit cartilage-degrading proteinases and reverse some effects of catabolic cytokines in vitro; together they produce synergistic suppression of cartilage destruction in vivo. The efficacy of IL-4, IL-10, and IL-13 in retarding cartilage damage may be related in part to their stimulatory effects on IL-1ra production, and their therapeutic application has been proposed as a means of restoring the cytokine balance in RA. IL-1ra is capable of blocking the actions of IL-1 if added at sufficiently high concentrations in vitro and was among the first agents to be developed for anti-cytokine therapy. However, TNF inhibitor therapy is more effective in RA than systemic IL-1ra, and intra-articular IL-1ra in OA joints requires delivery systems that maintain sufficiently high concentrations or local production.[113]

### Other Mediators

Chondrocytes in OA cartilage, especially those in clonal clusters, also express the pattern recognition receptors (PRRs), including Toll-like receptors (TLRs) and receptor for advanced glycation endproducts (RAGE). They are activated by ligands such as damage-associated molecular patterns (DAMPs), also known as alarmins, including high mobility group box-1 (HMGB1), S-100A8 (MRP8, calgranulin A) and S-100A9 (MRP14, calgranulin B), serum amyloid A (SAA), collagen and proteoglycan constituents, and calcium pyrophosphate or hydroxyapatite crystals. DAMPs or other products released from damaged cartilage are evidence of adaptive immunity due to interactions of T cells,[91] but during established, chronic OA their role in innate immunity, in which they promote the initiation and perpetuation of low-grade inflammation in the OA joint, is of current interest.[114,115]

S-100A8, S-100A9, and S-100A11 have critical roles in inflammatory arthritis and OA.[116,117] Activation of TLR or RAGE signaling drives inflammation-associated matrix catabolism through increased expression of inflammatory and catabolic genes, including MMP-3, MMP-13, and nitric oxide synthase (NOS)2 and increased ROS.[115,118] Pro-inflammatory cytokines, prostaglandins, ROS, and nitric oxide also promote oxidative stress and chondrocyte apoptosis by altering mitochondrial function.[119]

Other candidate innate effectors of the disease include the complement proteins, which are detected in synovial fluids of persons with OA by proteomic analysis and can be activated by DAMPs.[120] The classical, mannose-binding lectin, and alternative complement pathways all converge on C3 to activate the membrane attack complex (MAC)

formed from the complement effector C5b-C9. Knockout of the C5 and C6 components of MAC or pharmacologic treatment with CR2-fH attenuates cartilage damage in the medial meniscectomy mouse model.[121]

The peroxisome proliferation-activated receptors (PPARs) are a family of transcription factors that play roles in a broad spectrum of physiologic and pathologic processes, including skeletal homeostasis. PPARγ is activated by the endogenous ligand 15-deoxy-$\Delta^{12,14}$ prostaglandin $J_2$ ($PGJ_2$). PPARγ activation opposes the induction of cyclooxygenase (COX)-2, inducible (i)NOS, and MMPs and the suppression of aggrecan synthesis by IL-1. PPARα agonists may also protect chondrocytes against IL-1–induced responses by increasing the expression of IL-1ra. In OA, the focus has been on the roles of PPARγ in obesity and inflammation and its capacity to decrease cartilage degradation in animal models of OA.[122-125]

Among the proteins that may be induced in chondrocytes in response to abnormal stimuli is the cytokine-induced suppressor of cytokine signaling 3 (SOCS3), which acts as a feedback regulator to ameliorate adverse effects on chondrocyte functions.[126] SOCS proteins are inhibitors of cytokines that signal via the JAK/signal transducer and activator of transcription (STAT) pathway in multiple cell types, including T cells, macrophages, chondrocytes, synoviocytes, osteoclasts, and osteoblasts. de Andres et al.[127] examined the levels of SOCS proteins in cartilage specimens from a series of patients with OA and found that SOCS2 mRNA levels were markedly reduced in the OA chondrocytes compared with chondrocytes from normal cartilage.

Adipokines, including leptin, adiponectin, resistin, and visfatin, were identified originally as products of adipocytes and have roles in cartilage metabolism based on investigations in various experimental models.[128,129] Cytokines secreted by the white adipose tissue contribute to the low-grade inflammation in obesity-associated OA.[130] There is a balance between pro- and anticatabolic adipokines that are secreted by joint tissues, including the fat pad of the knee, suggesting complex interactions between systemic and local factors.[131]

Chemokines, which are small heparin-binding cytokines identified originally as chemotactic factors, are classified as C, CX3C, or CC molecules, indicating the presence of distinct N-terminal cysteine (C) residues. Chondrocytes, when activated by IL-1 and TNF, express several chemokines, including IL-8, monocyte chemoattractant protein (MCP)-1, MCP-4, macrophage inhibitory protein (MIP)-1α, MIP-1β, RANTES (regulated on activation normal T cell expressed and secreted), and growth-related oncogene (GRO)-α, as well as the receptors that enable responses to some of these chemokines (Table 3-5).[9,132] Normal and OA chondrocytes express the CC chemokines, MCP-1, MIP-1α, MIP-1β, and RANTES. RANTES increases expression of its own receptor, CCR5. MCP-1 and RANTES increase MMP-3, iNOS, IL-6, and MMP-1 expression, inhibit proteoglycan synthesis, and enhance proteoglycan release from the chondrocytes. The RANTES receptors CCR3 and CCR5, but not CCR1, are expressed in normal cartilage, whereas all three receptors are expressed in OA cartilage or after stimulation of normal chondrocytes by IL-1β.

**TABLE 3-5** Chemokines and Receptors in Chrondrocytes*

| Functional Name | Systematic Name | Chemokine Receptor |
|---|---|---|
| GROα | CXCL1 | CXCR1, CXCR2 |
| IL-8 | CXCL8 | CXCR1, CXCR2 |
| MCP-1 | CCL2 | CCR2 |
| MIP-1α | CCL3 | CCR1, CCR5 |
| MIP-1β | CCL4 | CCR5 |
| RANTES | CCL5 | CCR1, CCR3, CCR5 |
| SDF-1 | CXCL12 | CXCR4 |

*Chemokines are classified according to the positions of the first two cysteines (C) of the four conserved N-terminal cysteines: CC chemokine ligand (CCL), first two cysteines are adjacent; CXC chemokine ligand (CXCL), first two cysteines are separated by amino acid X other than cysteine; CCR, CC chemokine receptor; CXCR, CXC chemokine receptor.

GROα, Growth-related oncogene α; IL-8, interleukin-8; MCP-1, monocyte chemoattractant protein-1; MIP-1, macrophage inhibitory protein-1; RANTES, regulated on activation, normal T cell expressed and secreted; SDF-1, stromal-derived growth factor-1.

Stromal cell–derived factor 1 (SDF-1) can be detected in OA and RA synovial fluids, and its receptor, CXCR4, is expressed by chondrocytes but not by synovial fibroblasts, suggesting a direct influence of this chemokine on cartilage damage.[132] In addition to recruiting leukocytes to sites of inflammation in arthritic joints and mediating synovial fibroblast responses and actions, chemokines are capable of modulating chondrocyte functions that are associated with cartilage degradation.

## Cytokine Signaling Pathways Involved in Cartilage Metabolism

Although the receptors for IL-1 and TNF and associated adapter molecules are distinct, they share the capacity to activate some of the same signaling pathways (Figure 3-8). The major pathways induced by catabolic cytokines involve signal transduction by the stress-activated protein kinases, c-Jun N-terminal kinases (JNKs) and p38 kinases, and the NF-κB and PI3K pathways.[1,2,79,99,133] The JAK/STAT signaling pathway is important for signaling by gp130 cytokines, including IL-6 and OSM.[134] Specific adapter molecules involved in the pathways induced by TNF receptors, which are members of the TNF receptor superfamily, are different from the adapter molecules used by IL-1 signaling pathways. The TNF receptor pathway uses TNF receptor–associated factor 2 (TRAF2), TRAF6, and the receptor interacting protein kinase, whereas the IL-1 receptor pathway uses TRAF6, IL-1 receptor–associated kinase (IRAK), and evolutionarily conserved signaling intermediate in Toll pathways (ECSIT) as adapter molecules. Signaling through TNF-RI associated with TNF receptor–associated death domain (TRADD) activates apoptosis, whereas TNF-RII signaling through TRAF2 activates JNK and NF-κB.

In contrast to ERK1 and ERK2, p38 and JNK signaling pathways are weakly activated by growth factors. Studies in chondrocytes in vitro have shown that the p38 and JNK cascades mediate the induction of proteinases and proinflammatory genes by IL-1 and TNF. These pathways also may be activated in chondrocytes by mechanical stress and

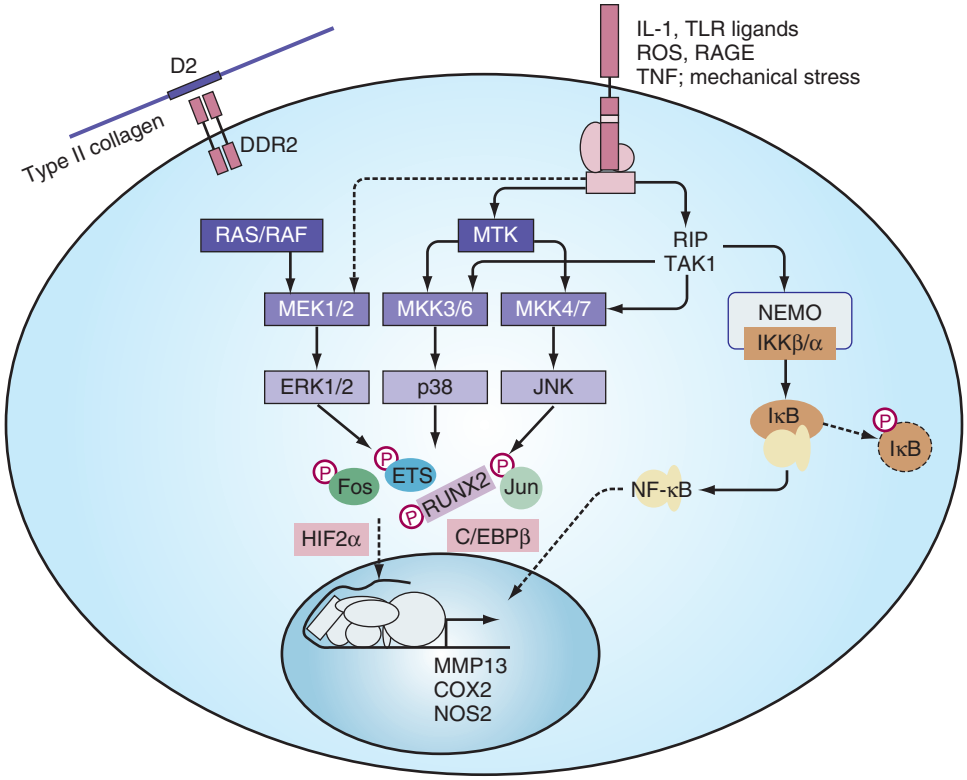

**Figure 3-8** Intra-cellular signaling pathways that regulate gene transcription in chondrocytes. Binding of the receptor tyrosine kinase, discoidin domain receptor (DDR) 2 to native type II collagen results in activation of RAS/RAF/MEK/ERK signaling in a manner independent of integrin- or cytokine-induced signaling. Interleukin (IL)-1, Toll-like receptor (TLR) ligand, reactive oxygen species (ROS), and receptor for advanced glycation end products (RAGEs) interact with the cell through distinct receptors that transduce phosphorylation events and initiate various protein kinase cascades. Binding of IL-1 to the type I IL-1 receptor (IL-1R1) leads to recruitment of the IL-1R accessory protein (IL-1RAcP). Cytoplasmic Toll/IL-1 receptor (TIR) domains of the receptor recruit MyD88 via its TIR, and the MyD88 death domain (DD) recruits IL-1 receptor–associated kinases (IRAK and IRAK2) to the receptor complex before being rapidly phosphorylated and degraded. The IRAKs mediate tumor necrosis factor receptor–associated factor 6 (TRAF6) oligomerization, initiating various protein kinase cascades. The major pathways involve activation of (1) the stress-activated protein kinases, p38 mitogen-activated protein kinase (MAPK), and c-Jun N-terminal kinase (JNK), which lead to activation of activator protein-1 (AP-1) (cFos/cJun), activating transcription factor-2 (ATF-2), E26 transformation-specific (ETS) factors, hypoxia-inducible factor (HIF)2α, Runx2, and CCAAT enhancer binding protein (C/EBP)β, among other transcription factors; and (2) inhibitor of κB (IκB) kinases α and β (IKK-α and IKK-β), which lead to activation of nuclear factor-κB (NF-κB). Tumor necrosis factor (TNF) also stimulates these pathways, but mainly via TRAF2. Other signaling pathways may influence the target gene responses, such as growth factor–induced or chemokine-induced phosphatidylinositol 3-kinase (PI3K) via the serine/threonine kinase, Akt/protein kinase B, and gp130 cytokine–induced Janus kinase (JAK)/signal transducer and activator of transcription (STAT) pathway. Responses of the target genes depend on the presence of DNA sequences within the respective promoters that bind to various transcription factors. COX, Cyclooxygenase; ERK, extra-cellular signal-regulated kinase; ETS, E26 transformation-specific; MMP, matrix metalloproteinase; NOS, nitric oxide synthase; TAK1, TGF-β–activated kinase 1. *(Modified from Goldring MB: Chondrogenesis, chondrocyte differentiation, and articular cartilage metabolism in health and osteoarthritis.* Ther Adv Musculoskelet Dis *4:269–285, 2012.)*

cartilage matrix products via integrins and other receptor-mediated events. Upregulation of IL-1 and TNF expression via mechanotransduction pathways suggests their involvement as secondary mediators in a feedback mechanism. At least four isoforms of p38 MAPK exist with different substrate specificities and differential effects on essential chondrocyte functions.

JNKs are serine threonine protein kinases that phosphorylate Jun family members, components of activator protein 1 (AP-1) transcription factors, and they exist in humans as three JNK isoforms: JNK1, JNK2, and JNK3. A potent JNK1/2 inhibitor, SP600125, which blocks inflammation and joint damage in animal models of RA, and other JNK isoform–specific inhibitors are useful tools for analyzing chondrocyte function in vitro and in vivo. Activated JNK is detected in OA, but not in normal cartilage, and JNK inhibition attenuates cytokine-induced chondrocyte responses.

Members of the NF-κB family orchestrate mechanical, inflammatory, and oxidative stress-activated processes in chondrocytes. NF-κBs are released from inhibitory IκBs or modified by the catalytic activities of the IκB kinase (IKK)α and IKKβ subunits of the IKK signalosome complex, permitting translocation of active NF-κB to the nucleus.[99] In response to a host of pro-inflammatory stimuli, IKKβ is the dominant IκBα kinase in vivo, whose activation is essential for the nuclear entry of canonical NF-κB heterodimers. NF-κB mediates the expression of cytokines and chemokines induced by fibronectin fragments, and inhibition of nuclear translocation or DNA-binding activity of NF-κB heterodimers of p65/p50 blocks pro-inflammatory and catabolic effects of IL-1 and TNF on chondrocytes. Chondrocyte phenotype appears to be subject to differential control by IKKβ-driven canonical NF-κB, which drives cartilage catabolism, and kinase-independent IKKα, which promotes hypertrophic conversion.[46]

The IKKβ-driven, canonical NF-κB pathway signaling also has effects on downstream transcriptional regulators, including HIF-2α, β-catenin, Runx2, and the E26 transformation-specific (ETS) factor, Elf3, thus linking inflammatory and oxidative stress responses with phenotypic and functional changes in chondrocytes.[39,40,135] In addition, NF-κB signaling plays a central role in disease progression and perpetuation, mediating a cascade of inflammatory responses triggered by advanced glycation end products, TLR ligands, or released ECM products, including fibronectin fragments, which lead to the continued expression of MMPs, aggrecanases, inflammatory cytokines, and chemokines and to an abnormal differentiation status.

## ROLE OF THE CHONDROCYTE IN CARTILAGE REPAIR

### Aging of Articular Cartilage

It is important, but often difficult, to distinguish among the effects of aging itself and diseases such as OA that become more common with increasing age.[136] In both cases, biochemical alterations in matrix composition are reflected in changes in cartilage structure.[137] The thickness of articular cartilage, as shown by MRI, decreases with increasing age. Heterogeneous depletion of glycosaminoglycans at the cartilage surface and fatigue fracture of superficial collagen bundles may contribute to the mild splitting and fraying of superficial cartilage, which is termed *fibrillation*. If fibrillation progresses into deeper layers of cartilage, abnormal multicellular clusters of chondrocytes that stain intensely for glycosaminoglycans are found at the base of clefts. These changes include decreased size and aggregation of aggrecan and increased collagen denaturation, resulting in loss of compressive stiffness and tensile strength.

Zonal differences in tensile strength and compressive resistance are related to differences in matrix composition and can be observed to change during the aging of adult articular cartilage and in response to traumatic damage. The territorial, or pericellular, matrix and the interterritorial matrix differ in the amounts and types of matrix proteins. The chondrocytes are normally surrounded by a 2 μm pericellular matrix, composed of a highly branched filamentous network of collagen VI tetramers, that serves as a scaffold for decorin, biglycan, perlecan, chondroadherin, hyaluronan, fibrillin-1, and PRELP.[15] The interterritorial region, in contrast, contains primarily a collagen II/XI fibril network, which binds decorin, fibromodulin, collagen IX, and COMP, and large numbers of intact aggrecan molecules attached via link protein to long chains of hyaluronic acid. In the deep zone, the interterritorial region most remote from the cells contains a larger number of degraded aggrecan molecules that lack the G3 domain.

Proteoglycans in aged cartilage have a wide range of sizes, with small forms resulting from low substitution of glycosaminoglycan residues and shorter lengths compared with glycosaminoglycans in young articular cartilage. Unsubstituted proteoglycan core proteins of aggrecan and biglycan are detectable in articular cartilage from elderly subjects. Hyaluronan content increases in aged cartilage, but with reduced mean chain length, and link protein seems to be fragmented. Collagen fibrils become thinner with age and are less densely packed. Nonenzymatic glycation results in the formation and accumulation of the advanced glycation end product pentosidine in long-lived proteins, including cartilage collagen and aggrecan. Such biochemical changes may result in part from changes in chondrocyte synthetic function and from increased susceptibility of the matrix to degradation. Increased and more extensive collagen degradation can be observed in cartilage from older, healthy persons, and, similar to cartilage in early OA, the damage is concentrated closer to the articular surface and co-localizes with MMP-13 activity. (See Chapter 98 for a detailed discussion of the pathogenesis of OA.)

### Aging Chondrocyte

Chondrocyte function, including mitotic and synthetic activity, deteriorates with age.[136] Degradative changes are generally due to the actions of proteinases and are, at least in part, the cumulative consequences of adverse conditions, such as mechanical insults or inflammation, to which the chondrocyte is exposed throughout life. Deficiencies in cartilage matrix proteins also may disrupt chondrocyte-matrix interactions that are important to cell survival. The decline in chondrocyte number may be attributed to increased cell death with age. Although programmed cell death, or apoptosis, increases with age in adult rats and mice, this may be due to skeletal growth that occurs throughout life in these animals. In human adult cartilage, apoptotic cell removal does not seem to be common, however. Replicative senescence, detected as β-galactosidase activity and decreased telomere length, has been proposed to contribute to age-related changes in the proliferative potential of adult articular chondrocytes.[138,139] Furthermore, TGF-β, FGFs, IGF-I, and other anabolic factors that support cartilage matrix biosynthesis are expressed at declining levels with aging, or their activities are downregulated.[136]

Chondrocytes use autophagy as an efficient housekeeping program to maintain cellular function and homeostasis by removing damaged or malfunctioning cellular structures, eliminating exogenous cellular aggressors, and providing alternative sources of energy during endoplasmic reticulum (ER) stress, hypoxia, starvation, and other adverse events.[140,141] The loss of autophagy in articular cartilage during aging is associated with cell death and increasing OA severity because the chondrocyte is less resistant to mechanical or inflammatory stress.[142] Autophagy occurs by lysosome- or endosome-mediated mechanisms.

Also compromised during aging is the unfolded protein response (UPR), which is a nonlysosomal pathway for ubiquitin/proteasome degradation of unfolded proteins eliminated from the ER.[143] The UPR enables chondrocyte survival in response to ER stress during growth plate development[144] but also during inflammatory, mechanical, and oxidative stress in articular cartilage via C/enhancer binding protein (EBP) homologous protein (CHOP) and X-box protein 1 (XBP1).[143] Also related to autophagy are the classic cell survival signals, PI3K and its downstream target serine-threonine kinase (AKT).[79] In addition, the impairment of chondrocyte mitochondrial function has emerged as a mechanism involved in impaired autophagy and deregulated bioenergetics during aging and OA development.[119]

## Markers of Cartilage Matrix Degradation and Turnover

With increasing knowledge of the composition of the cartilage matrix, molecular markers in body fluids have been identified for monitoring changes in cartilage metabolism and for assessing joint damage in persons with arthritis.[11] Molecules originating from the articular cartilage, including aggrecan fragments containing chondroitin sulfate and keratan sulfate, type II collagen fragments, collagen pyridinoline cross-links, and COMP, usually are released as degradation products as a result of catabolic processes. Specific monoclonal antibodies have been developed for analyzing OA and RA body fluids for products of proteoglycan or collagen degradation (catabolic epitopes) or synthesis of newly synthesized matrix components (anabolic neoepitopes), which represent attempts to repair the damaged matrix. Different monoclonal antibodies can distinguish subtle biochemical differences in chondroitin sulfate or keratan sulfate chains that result from degraded versus newly synthesized proteoglycans. Such epitopes can be detected in the synovial fluids and sera of patients with OA and RA, and the synovial fluid to serum ratio has been suggested as a potential diagnostic indicator. The degradation of aggrecan in cartilage has been characterized using antibodies 846, 3B3(−), and 7D4, which detect chondroitin sulfate neoepitopes; 5D4, which detects keratan sulfate epitopes; and the VIDIPEN and NITEGE antibodies, which recognize aggrecanase and MMP cleavage sites within the interglobular G1 domain of aggrecan.[101,106]

Similarly, it is possible to monitor the synthesis of type II collagen by measuring serum and synovial fluid levels of the carboxyl-terminal propeptide (CPII), and urinary excretion of hydroxylysyl pyridinoline cross-links may indicate collagen degradation. Specific antibodies that recognize epitopes on denatured type II collagen at the collagenase cleavage site are promising diagnostic reagents. These include the C12C antibody (previously known as *Col2-3/4C Long mono*), which has been used to detect cleavage of the triple helix of type II collagen in experimental models and in OA and RA cartilage. The ratios of these markers to the synthetic marker, CPII, are associated with a greater likelihood of radiologic progression in persons with OA. These biomarker assays have been used as research tools and are currently being developed and validated as diagnostic tools for monitoring cartilage degradation or repair in OA and RA patient populations and for assessment of treatment (see Chapters 71 and 100).[11] Although a single marker may be insufficient, eventually it may be possible to identify a combination of biomarkers that discriminate between different stages of OA in different patient populations.

## Repair of Articular Cartilage

Articular cartilage has a poor capacity for regeneration, and pharmacologic enhancement of cartilage repair would have considerable potential in the treatment of arthritides and intra-articular fractures. The extent of intrinsic repair of a cartilage defect depends on the depth of the lesion and whether the defect penetrates the subchondral bone plate.[4] Repair of superficial defects occurs if the chondrocytes remain viable. Because of the avascularity of cartilage, it differs from most other tissues in its response to injury. The vascular-dependent inflammatory and reparative phases of the classic healing response are unavailable. Partial defects generally do not regenerate because resident chondrocytes cannot migrate into the defect, and there is no vascular access for progenitor cells. Deep cartilage defects with disruption of the subchondral bone plate initiate vascular responses, however, including bleeding, fibrin clot formation, and inflammation, which permit cell invasion from the blood or underlying bone marrow. The lesion becomes filled by granulation tissue, which eventually is replaced by fibrocartilage, but rarely by true hyaline cartilage. Current procedures for cartilage repair include joint lavage, tissue debridement, microfracture of the subchondral bone, and transplantation of autologous or allogeneic osteochondral grafts, in addition to the ultimate therapy of total joint replacement.[4] These procedures may lead to the formation of fibrous tissue, chondrocyte death, and further cartilage degeneration and have variable success rates.

Transplantation of cultured autologous chondrocytes has been used successfully to repair small, full-thickness lesions in knee cartilage in young adults with sports injuries. Evidence of successful repair has been shown by turnover and remodeling of the initial fibrocartilaginous matrix formed by transplanted chondrocytes as the result of enzyme degradation and new synthesis of type II collagen. The donor site, although not load bearing, may undergo significant morbidity and osteoarthritic changes. Such procedures, however, show little difference in efficacy compared with microfracture of subchondral bone.[4]

Major challenges for cartilage repair include restoration of the three-dimensional collagen structure and integration of the newly synthesized matrix with resident tissue.[4] Novel approaches using autologous chondrocytes genetically engineered ex vivo to express anabolic factors have been explored to promote differentiation before implantation in the defect.[145] Because IGF-1 and TGF-β/BMP and FGF family members have roles in chondrogenesis and articular cartilage maintenance, they have been used as additive factors in tissue engineering strategies. The introduction of these factors into joints directly or by in vivo or ex vivo gene delivery or via injectable or implantable carriers has been investigated for the repair of small defects in animal models. Gene transfer of combinations of anabolic factors and inhibitory cytokines combined with cartilage engineering approaches may be a long-term goal for repair of extensive defects in patients with RA or late-phase OA and for prevention of further damage.

The predominant research strategy aimed at engineering functional cartilage with the identical properties of the native tissue has been to increase the accumulation of a cartilaginous matrix by exposing cells to anabolic agents such as those previously discussed, either through exogenous addition of recombinant proteins or genetic manipulation of the cells to overexpress them.[146] This work has led to development of scaffold materials, identification of viable cell sources and culture conditions, including growth factor delivery and mechanical stimulation, as well as approaches for delivering cells alone or in a scaffold to the injury site.[147] However, we are far from achieving a construct with the mechanical stability and lubricating properties of native cartilage. Successful cartilage tissue engineering strategies

must also include retention of key matrix components within the construct over an extended life span and under inflammatory conditions and integration with the host tissue. Furthermore, the restoration of the pericellular matrix will be essential for any successful tissue engineering strategy.[15]

Recent investigations have focused on scaffolds with the mechanical and material properties of the osteochondral unit that will integrate with the host tissue and attract migration of chondrocytes or osteochondral progenitors from the subchondral bone.[147] Although these strategies for the future based on in vitro and in vivo studies are promising, many challenges remain, especially for cell-mediated cartilage repair. Among the cell sources are MSCs, which can be obtained from autologous adipose tissue, bone marrow, synovium, or muscle; they can be expanded ex vivo in conditions that promote chondrogenesis, incorporated into scaffolds, and/or used as gene delivery vehicles to the site of cartilage damage.[145] Although adult articular chondrocytes have little intrinsic repair capacity, the potential of a small population of cartilage-derived stem or progenitor cells to be stimulated in situ is the subject of current investigations.[148]

## CONCLUSION

As the single cellular component in adult articular cartilage, chondrocytes are responsible for maintaining the ECM components in a low-turnover state. The composition and organization of matrix macromolecules, unique to this tissue, are determined during chondrocyte differentiation in embryonic and postnatal development of cartilage. Adult chondrocytes exist in a hypoxic environment within articular cartilage. They are inactive metabolically, partially as a result of the absence of blood vessels and nerves, and display a rounded structure that reflects their quiescent state. Chondrocyte culture models have been developed with the aim of maintaining differentiated phenotypes, characterized by the major collagen and proteoglycan constituents, type II collagen and aggrecan. Chondrocytes interact with specific ECM components via cell surface receptors, including integrins, annexins, syndecans, DDR2, and CD44.

Studies in vitro and in vivo have shown that adult articular chondrocytes are capable of responding to biologic and mechanical stimuli that are anabolic or catabolic. Anabolic factors include members of the TGF-β/BMP and FGF families and IGF-I. Catabolic factors include pro-inflammatory cytokines, chemokines, DAMPs/alarmins, and adipokines, which stimulate the synthesis of matrix-degrading proteinases, such as MMPs and aggrecanases, in chondrocytes and increase intra-cellular events associated with inflammatory, mechanical, and oxidative stress. Many of the signaling pathways and transcription factors that mediate the responses of chondrocytes to these factors have been elucidated, but how they orchestrate specific chondrocyte functions is complex and is not fully understood. Under physiologic conditions, the adult articular chondrocyte maintains a stable equilibrium of low-turnover replacement of matrix components. Adult chondrocytes have a poor capacity for mediating effective repair of extensive cartilage lesions, and this capacity declines with age. Age-related changes in chondrocyte function decrease the ability of cells to maintain the tissue, and there is decreased responsiveness to anabolic growth factors. Further understanding of how the adult articular chondrocyte functions within its unique environment would aid in the development of rational strategies for maintaining homeostasis and protecting against cartilage damage.

CHAPTER 4

# Biology, Physiology, and Morphology of Bone

Georg Schett

**KEY POINTS**

- Intramembranous or endochondral ossification generates bone tissue.
- Bones consist of a dense cortical shell and sponge-like trabecular network.
- Bone formation depends on metabolically active osteoblasts synthesizing matrix proteins.
- Resorption of bone is mediated by multinucleated osteoclasts.
- The most abundant cell type in bone is the osteocyte.
- Bone is continuously rebuilt, a process known as *bone remodeling*.
- The immune system, in particular T lymphocytes, influences bone remodeling.
- Neuroendocrine loops exert systemic control on bone remodeling.

## STRUCTURE AND COMPOSITION OF BONE

Bone is a specialized connective tissue that assists in (1) locomotion, by providing the insertion site of the muscles; (2) protection of the internal organs and the bone marrow; and (3) metabolic function, such as storage and provision of calcium to the body. Bone consists of cells and the extracellular matrix, which is composed of type I collagen fibers and a number of noncollagenous proteins. The specific composition of the bone matrix allows its mineralization, which is a specific feature of bone.

The two major types of bones are flat bones, which are built by intramembranous ossification, and long bones, which emerge from endochondral ossification. Intramembranous bone formation is based on the condensation of mesenchymal stem cells, which directly differentiate into bone-forming osteoblasts. In contrast, during endochondral ossification of the long bones, the mesenchymal stem cells first differentiate into chondrocytes that will later be replaced by osteoblasts. Long bones consist of the (1) epiphyses, which are protrusions at the ends of the long bones; (2) diaphysis, constituting its shaft; and (3) metaphyses, which are located between the epiphysis and the diaphysis (Figure 4-1). The metaphysis is separated from the epiphysis by the growth plate, a proliferative cartilage layer that is essential for the longitudinal growth of bones. After the growth is completed, this cartilage layer is entirely remodeled into bone.

The external shape of bones is formed by a dense cortical shell (cortical or compact bone), which is particularly strong along the diaphysis, where the bone marrow is located. The cortical bone shell becomes progressively thinner toward the metaphyses and epiphyses, where most of the trabecular bone is located. Trabecular bone (also called *cancellous bone*) is a sponge-like network consisting of myriads of highly interconnected bony trabeculae. The outer and the inner surfaces of cortical bone are covered by layers of osteogenic cells, termed the *periosteum* and the *endosteum*, which are involved in the growth of width by bone apposition at the periosteal sites and bone resorption at the endosteal sites.

Although cortical and trabecular bone is composed of the same cells and the same matrix components, there is a substantial difference between these two forms of skeletal tissue. Cortical bone almost exclusively consists of mineralized tissue (up to 90%), allowing it to fulfill its mechanical requirements. In contrast, only 20% of trabecular bone is mineralized tissue, with the bone marrow, blood vessels, and a network of mesenchymal stem cells constituting the remainder of the bone. As a consequence, trabecular bone shares a vast surface with the nonmineralized tissue, which is the basis for the metabolic function of bone, necessitating a high level of communication between the bone surface and the nonmineralized tissue.

### Bone Matrix

The key protein component of bone is type I collagen. Collagen fibers follow specific directions, forming the basis for the lamellar structure of bone. This lamellar structure, which can be visualized when examining bone in the polarized light, allows dense packaging, resulting in optimal resistance to mechanical load. The lamellar collagen structures can be assembled in parallel (e.g., along the cortical bone surfaces and inside the bony trabeculae) or concentrically around blood vessels embedded in the Haversian channels of the cortical bone. Upon rapid deposition of new bone, such as during fracture healing, this lamellar structure is missing, and the bone is then called *woven bone*. Woven bone is consecutively remodeled into lamellar bone, which is also considered "mature" bone. The composition of the collagen backbone also assists in the deposition of spindle- or plate-shaped hydroxyapatite crystals, which contain

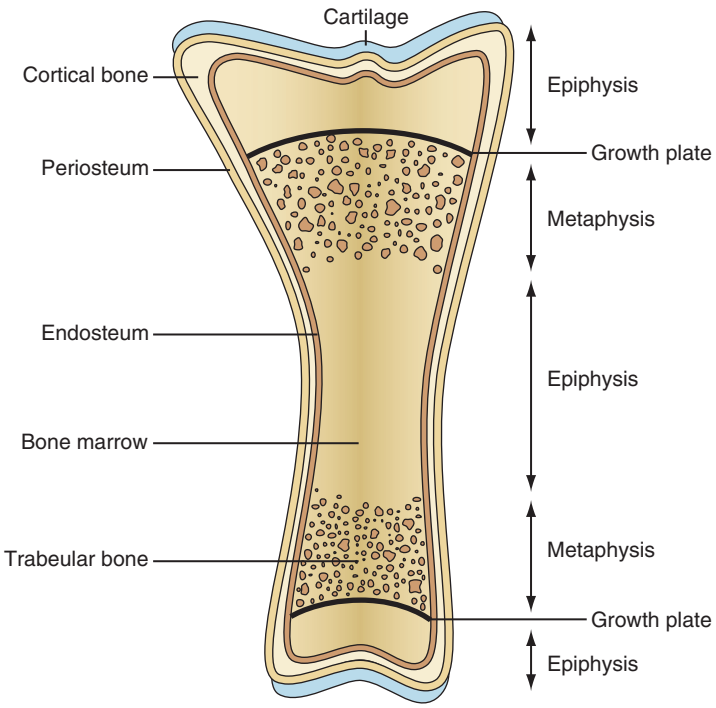

**Figure 4-1** Long bones consist of the epiphyses separated by growth plates from the metaphyses, which contain most of the trabecular bone. The outer lining of bone is the dense cortical bone, which is covered by the periosteum (outer surface) and the endosteum (inner surface). The latter connects bone to the bone marrow. The bony end plates are covered by the articular cartilage, consisting of a mineralized deep zone and a nonmineralized surface zone.

calcium phosphate, thus allowing the calcification of the bone matrix.

In addition to type I collagen, other so-called noncollagenous proteins also exist in bone. Some of them, such as osteocalcin, osteopontin, and fetuin, are mineralization inhibitors, which serve to balance the degree of mineralization of the skeletal tissue. Aside from their intrinsic function in bone, noncollagenous proteins also exert important metabolic functions, such as the control of energy metabolism by osteocalcin.

## Bone Cells: Osteoblasts

Osteoblasts are the bone-forming cells that derive from the mesenchymal stem cells of the bone marrow, which also form chondrocytes, myocytes, and adipocytes. Osteoblasts are cuboid-shaped cells that form clusters covering the bone surface. They are metabolically highly active, synthesizing the collagenous and noncollagenous bone matrix proteins that are excreted and then deposited between the osteoblasts and the bone surface. This newly built matrix, which is not yet calcified, is termed the *osteoid*. The lag phase between osteoid deposition and its mineralization is approximately 10 days. Osteoblast differentiation depends on the expression of two key transcription factors, Runx2 and its target Osterix 1, which confer the differentiation of these cells into osteoblasts in response to external stimuli.[1] Prostaglandin $E_2$ ($PGE_2$), insulin-like growth factor (IGF)-1, parathyroid hormone (PTH), bone morphogenic proteins (BMPs), and Wingless and Int-1 (Wnt) proteins are key stimuli for osteoblast differentiation.[2,3] For instance, $PGE_2$ is an important anabolic factor for bone and induces the expression of bone sialoprotein and alkaline phosphatase in mesenchymal cells. BMPs and transforming growth factor (TGF)-β, which shares structural similarities with BMPs, foster osteoblast differentiation by activating intra-cellular Smad proteins. Finally, Wnt proteins, a family of highly conserved signaling molecules, are potent stimulators of osteoblast differentiation. Wnt proteins bind to surface receptors on mesenchymal cells such as Frizzled and LRP5, eliciting activation and nuclear translocation of the transcription factor β-catenin, which induces the transcription of genes involved in osteoblast differentiation. Wnt proteins thereby act not only in close synergy with BMPs but also cross-talk to the receptor activator of nuclear factor-κB ligand (RANKL)–osteoprotegerin (OPG) system, which is involved in the differentiation and function of bone-resorbing osteoclasts.

## Bone Cells: Osteocytes

Osteocytes are by far the most abundant cell type within bone. One cubic millimeter of bone contains up to 25,000 osteocytes that are well connected with each other and the bone surface by small tubes (canaliculi), constituting a large and dense communication network inside the bone with similarities to the nervous system. The surface of this network of lacunae, which contains the osteocytes, and the canaliculi, which contains the interconnecting filaments of the osteocytes, covers an area of 1000 to 4000 square meters. Osteocytes are derived from osteoblasts, which are subsequently entrapped in the bone matrix.[4] Osteocytes, however, also start to express genes that are specific for these cells and are not found in other cells, such as osteoblasts. One of the

most interesting products of the osteocyte is sclerostin, a secreted molecule that binds lipoprotein receptor–related proteins (LRPs) and blocks Wnt-stimulated bone formation.[5] Consistent with its function as an inhibitor of bone formation, overexpression of sclerostin leads to low bone mass, whereas deletion of sclerostin leads to increased bone density and strength. This effect has recently been successfully used as a therapeutic strategy to increase bone mass by inhibiting sclerostin by a specific antibody.[6] Loss-of-function mutations in the human *SOST* gene that encodes sclerostin entail increased bone mass, a disease termed *sclerosteosis*.[7] Several local and systemic factors have been suggested as possible regulators of sclerostin expression by osteocytes. For instance, intermittent administration of PTH, which is associated with strong anabolic effects on the bone, potently inhibits sclerostin expression.

## Bone Cells: Osteoclasts

Osteoclasts are multinucleated cells that contain up to 20 nuclei and are unique in their ability to resorb bone.[8,9] They are directly attached to the bone surface and build resorption lacunae (Howship lacunae). Apart from their multiple nuclei, another characteristic of the osteoclast is the *ruffled border*, a highly folded plasma membrane facing the bone matrix and designed to secrete and resorb proteins and ions into the space between the osteoclast and bone surface (Figure 4-2). The space between this ruffled border and the bone surface is the place where bone resorption occurs. It is sealed by a ring of contractible proteins and tight junctions because it represents one of the few regions of the human body where a highly acidic milieu is found. Bone degradation by osteoclasts consists of two major steps: first, demineralization of inorganic bone components, and second, removal of organic bone matrix. To demineralize bone, osteoclasts secrete hydrochloric acid through proton pumps into the resorption lacunae. This proton pump requires energy that is provided by an adenosine triphosphatase (ATPase), allowing the enrichment of protons in the resorption compartment, which, in fact, represents an extra-cellular lysosome. In addition to protons and chloride, osteoclasts release matrix-degrading enzymes, including tartrate-resistant acid phosphatase (TRAP), lysosomal cathepsin K, and other cathepsins. Cathepsin K can effectively degrade collagens and other bone matrix proteins. Consequently, inhibitors of cathepsin K block osteoclast function and slow down bone resorption.

Osteoclasts originate from hematopoietic monocytic precursor cells and, upon the influence of specific signals, undergo a series of differentiation steps to become mature osteoclasts. Essential signals for osteoclast differentiation are macrophage colony-stimulating factor (M-CSF) and RANKL. During this differentiation and maturation process, osteoclasts acquire specific markers such as TRAP, fuse to multinucleated giant cells, and polarize on contact to bone. Osteoclastogenesis depends on an adequate microenvironment, which provides essential signals such as M-CSF and RANKL and certain cytokines such as tumor necrosis factor (TNF), which further enhance osteoclast differentiation. Mesenchymal cells such as preosteoblasts express M-CSF and RANKL and can induce osteoclast formation, highlighting the close interaction between bone formation and bone resorption.

RANKL, a TNF superfamily member, is a surface molecule expressed by osteocytes, preosteoblasts, and activated T cells.[10-12] Under steady-state conditions, its expression is induced in cells of the osteoblastic lineage in response to osteotropic factors such as vitamin D, PTH, and

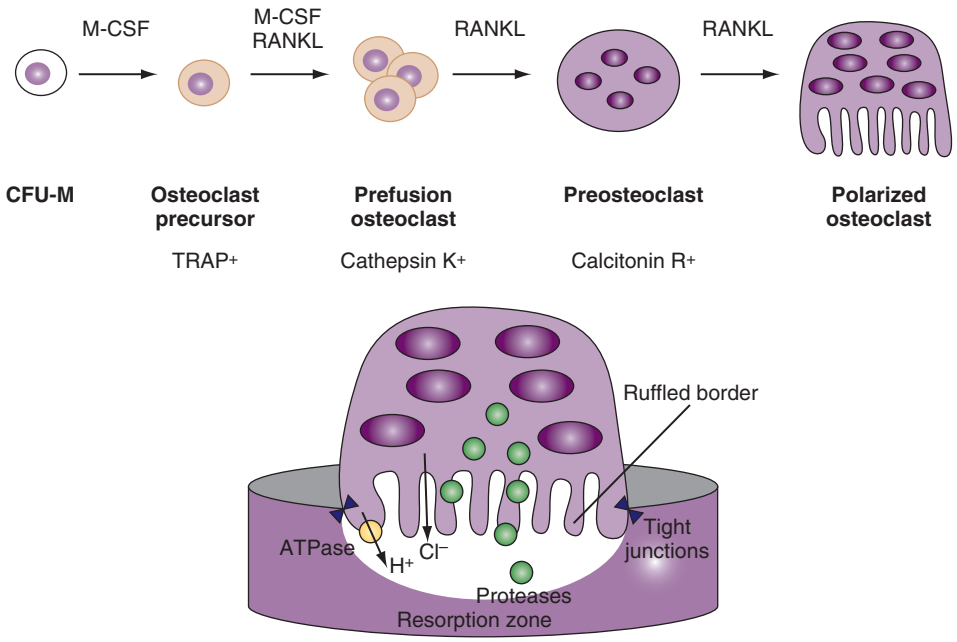

**Figure 4-2** Osteoclasts form from mononuclear precursors (colony-forming unit macrophages [CFU-M]), which differentiate into mononuclear osteoclast precursors. These cells fuse and build a polykaryon, forming a preosteoclast. Final differentiation is characterized by cell polarization and acquisition of a ruffled border. ATPase, Adenosine triphosphatase; M-CSF, macrophage colony-stimulating factor; RANKL, receptor activator of nuclear factor-κB ligand; TRAP, tartrate-resistant acid phosphatase.

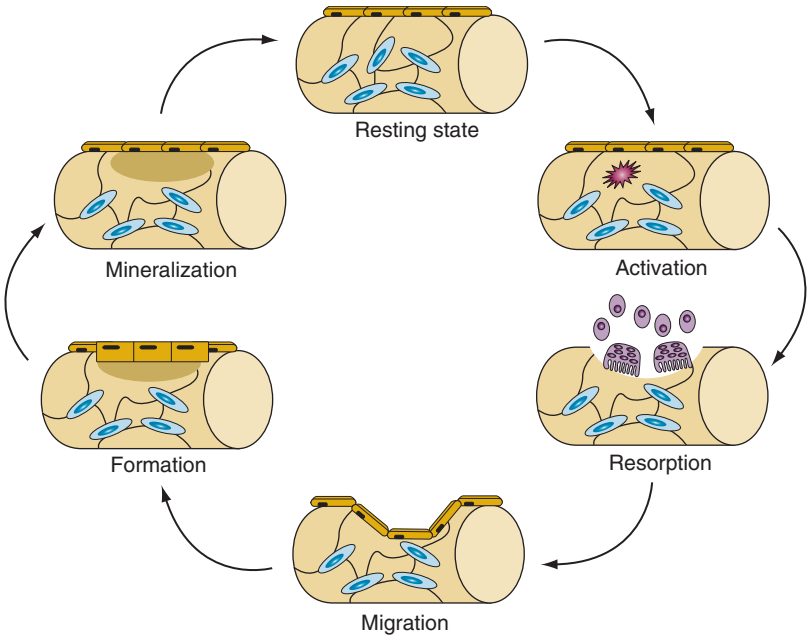

**Figure 4-3** Sequence of bone remodeling with *activation* characterized by sensing of damage by osteocytes, *resorption* by osteoclast differentiation and removal of bone matrix, *migration* of bone-lining mesenchymal cells into the lacuna, *formation* of new matrix by osteoblasts (cuboid cells), and *mineralization* of the newly synthesized matrix.

prostaglandins, whereby the nuclear factor peroxisome proliferator-activated receptor–beta represents an essential checkpoint in the regulation of RANKL expression.[13] Moreover, inflammatory cytokines such as TNF, interleukin (IL)-1, and IL-17 can induce RANKL expression.[14-17] RANKL is essential for the final differentiation steps of osteoclasts, as well as for their bone-resorbing capacity, by engaging its receptor RANK on monocytic osteoclast-precursor cells. The interaction of RANKL with its receptor RANK is modulated by OPG, a secreted glycoprotein, which has been identified as a soluble factor that strongly suppresses osteoclast differentiation both in vitro and in vivo. Interestingly, OPG expression is induced by estrogens, which explains the increase in osteoclast numbers and enhanced bone resorption during menopause. In accordance, RANKL-deficient mice display severe osteopetrosis as a result of the lack of osteoclasts. With regard to the central role of the RANKL-RANK-OPG signaling system in bone resorption, researchers are increasingly interested in the therapeutic targeting of this system in human disease, and recent clinical trials involving post-menopausal osteoporosis have revealed the potent anti-resorptive effect of a neutralizing RANKL antibody (denosumab).[18] Beyond RANKL-RANK interactions, other important pro-osteoclastogenic signaling pathways are based on the triggering receptor expressed on myeloid cells (TREM) 2, which interacts with the tyrosine kinase DAP12 and the osteoclast-associated immunoglobulin-like receptor (OSCAR). Both molecules are strong enhancers of osteoclastogenesis.[19]

## Bone Remodeling Process

Developmental bone growth, postdevelopmental maintenance and repair of bone, and provision of calcium from the bone depend on a dynamic process called *bone remodeling* (Figure 4-3). Factors yet unknown, which may likely be of mechanical nature and sensed by the osteocytes, initiate bone remodeling at a specific site. The death of osteocytes and the resulting metabolic changes leading to a lack of silencers for bone turnover, like sclerostin, may govern this activation process. It is followed by a resorptive phase dominated by osteoclast-mediated degradation of the bone matrix, resulting in a resorption lacuna. The naked bone surface inside this lacuna is subsequently populated by mesenchymal cells immigrating from the neighboring bone surface, which start differentiating into osteoblasts and produce the new bone matrix (also termed *osteoid*). This matrix then mineralizes, and the bone again returns to its resting state. This entire bone remodeling process takes about 3 to 6 months. Adults continuously remodel their skeleton, and this process occurs even faster during childhood and adolescence. In adults the entire skeleton is remodeled in 7 to 10 years, which indicates that we fully replace our skeleton several times during our lifetime. Most of the bone remodeling happens in the trabecular bone, which promotes the building of an optimal inner microstructure adapted to the individual mechanical demands. Trabecular bone is the leading structure in the vertebral bodies (constituting up to two-thirds of the bone substance) and in long bones such as the femurs (constituting about 50% of the bone substance).

Normal physiologic circumstances ensure a balance between bone formation and bone resorption to maintain skeletal homeostasis. This bone remodeling process requires a tight mutual regulation of bone resorption by osteoclasts and bone formation by osteoblasts, a phenomenon called *coupling*. Coupling is regulated on at least three different levels: (1) by a direct interaction between osteoblasts and osteoclasts; (2) by local interactions between the immune

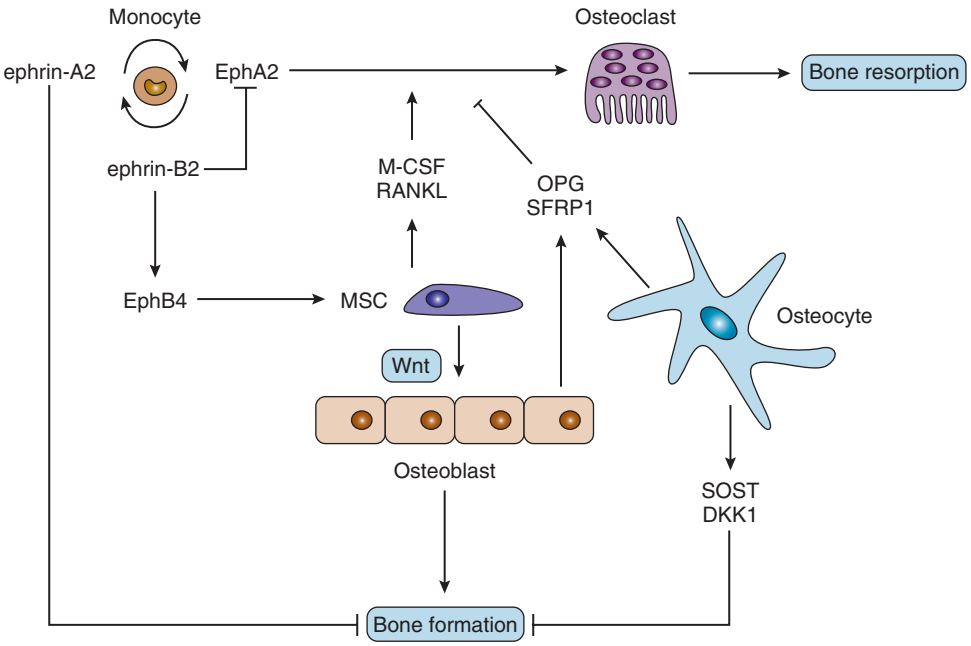

**Figure 4-4** Mesenchymal stem cells (MSCs) and preosteoblasts generated macrophage colony-stimulating factor (M-CSF) and receptor activator of nuclear factor-κB ligand (RANKL), supporting osteoclast differentiation. In contrast, mature osteoblasts suppress osteoclast differentiation by expression of osteoprotegerin (OPG) and secreted frizzled-related protein 1 (SFRP1). The ephrin-A2 system is an autocrine stimulator for osteoclasts and also blocks bone formation. In contrast, the binding of ephrin-B2 to its receptor ephrin-B4 stimulates osteoblast differentiation. Osteocyte-derived mediators such as sclerostin (SOST) and dickkopf-1 (DKK1) suppress bone formation by inhibiting the Wnt pathway.

system and bone cells; and (3) by neuroendocrine systemic control of bone metabolism.

## Direct Interactions between Osteoblasts and Osteoclasts

A proper coupling between bone formation and bone destruction is essential to maintain bone integrity (Figure 4-4). This coupling process involves two main mechanisms; the first is the expression of the essential pro-osteoclastogenic cytokines by the osteoblast lineage, and the second involves the ephrin ligand/ephrin receptor bidirectional signaling.[20,21] Preosteoblasts are the main pro-osteoclastogenic cells in normal physiologic conditions and provide the first level of coupling between bone formation and bone resorption. In response to Wnt signaling, osteoblasts slowly lose their supportive activity for osteoclasts when they mature toward more mineralizing cells and then become the bone-embedded osteocytes. They then secrete antiosteoclastogenic molecules such as OPG and the Wnt inhibitors sclerostin, dickkopf-1, and secreted frizzled-related protein 1 (SFRP1), which either block osteoclast differentiation (OPG) or also inhibit the further differentiation of osteoblasts. A second level of coupling involves the expression of ephrin ligands on the surface of osteoclast progenitors that can bind to ephrin receptors and activate their tyrosine kinase activity. Two ephrin ligands regulate bone remodeling. The first, ephrin-B2, binds to the receptor EphB4 on osteoblast progenitors, increasing their differentiation and stimulating bone formation. The second, ephrin-A2, acts in an autocrine manner by binding to the EphA2 receptor on the osteoclasts, promoting their differentiation in a paracrine manner on the osteoblasts, thus inhibiting their differentiation.

## Bone Remodeling by the Immune System

Aside from the reciprocal regulation of osteoblasts and osteoclasts, bone remodeling is also controlled by the immune system. Insights into the control of bone by the immune system have led to a new research field known as *osteoimmunology*, which has defined new pathways involved in immune regulation of post-menopausal osteoporosis and bone loss during inflammatory diseases.[22-24] Importantly, T cells influence the differentiation of osteoclasts, and hence activated T cells express RANKL, which does not only stimulate osteoclastogenesis but also promotes the survival of dendritic cells.[25] RANKL expression has been found on various subsets of proliferative T cells (CD8 and CD4 and Th1 and Th2), as well as on FoxP3-expressing regulatory T cells (Tregs). Despite consistent expression of RANKL on various T cell lineages, individual T cells exert substantially different functions on the osteoclast, allowing a fine regulation of bone remodeling by the immune system. For instance, Th17 cells stimulate osteoclast differentiation via the production of IL-17.[17] Moreover, a subset of T cells expressing the IL-23 cytokine receptor is involved in bone remodeling, specifically at the insertion sites of the tendons.[26] In contrast, other T cell lineages express strong inhibitors of osteoclastogenesis, such as interferon (IFN)-γ in the case of Th1 cells, IL-4 in the case of Th2 cells, or cytotoxic T lymphocyte–associated antigen-4 (CTLA-4) in the case of regulatory T cells, and thereby provide protection from bone loss.[27-30]

### Systemic Control of Bone Remodeling by Neuroendocrine Mechanisms

Bone remodeling is regulated not only locally but also by various systemic hormonal pathways, including the sex hormone and the growth hormone (GH)/IGF axes. In addition, two major systemic neuroendocrine regulators of bone homeostasis co-regulate bone, fat, and energy metabolism.[31,32] The two central players of this systemic loop seem to be osteocalcin and leptin. Osteocalcin is a hormone produced by mature osteoblasts and acts on the β cells of the pancreas to stimulate proliferation and thus insulin production in response to leptin.[32] In addition, osteocalcin can directly stimulate adipocytes to regulate insulin sensitivity. Leptin is a peptide hormone produced by adipocytes of the white adipose tissues. Leptin deficiency causes obesity and increased bone mass. Although the increased fat mass is certainly linked to the role of leptin in controlling appetite, the effect of leptin on bone and fat can be dissociated. Indeed, bone formation is negatively regulated by leptin through a hypothalamic pathway: the β-adrenergic sympathetic nervous system that mediates decreased osteoblast proliferation via the induction of clock genes in osteoblasts.[33,34] The question of how leptin regulates bone formation is debated. However, two potential hypothalamic relays have been identified. The first relay is the NPY peptide, a repressor of bone formation, which is silenced by leptin.[35] The second downstream modulator of leptin is neuromedin U, which inhibits clock gene expression and increases osteoblast proliferation.[36] These observations suggest that disturbance of the metabolic loops linking adipogenesis, osteogenesis, and insulin production have profound consequences on bone homeostasis.

## CONCLUSION

Bone is continuously remodeled by bone-resorbing osteoclasts and bone-forming osteoblasts. This remodeling process allows the optimal adaptation of the bone architecture to individual demands and tight control of calcium homeostasis. Local factors control the bone remodeling process on the basis of osteoclast-osteoblast interactions, as well as by systemic immune and neuroendocrine factors controlling the bone-resorbing and bone-forming cells.

CHAPTER 5

# Muscle: Anatomy, Physiology, and Biochemistry

Mark S. Miller • Bradley M. Palmer • Michael J. Toth • David M. Warshaw

**KEY POINTS**

- The structure and function of skeletal muscle and its neural recruitment pattern can change rapidly in response to activity level (i.e., plasticity).
- The smallest functional unit of muscle, the sarcomere, is composed of an almost crystalline array of filamentous proteins that convert metabolic energy into force and movement.
- Muscles are attached to the skeleton through collagenous tendons.
- Skeletal muscle contraction is controlled by the central nervous system through depolarization of specific efferent neurons called *motor neurons.*
- Motor neurons innervate and depolarize muscle fibers through cholinergic synapses called *neuromuscular junctions.*
- Afferent neurons provide the central nervous system with sensory information required for effective control of movement and posture.
- Force is transmitted to the exterior through two sets of protein cell adhesion complexes: integrins and dystroglycans.

Approximately 660 skeletal muscles support and move the body under the control of the central nervous system. These muscles constitute up to 40% of adult human body mass. Most skeletal muscles are fastened by collagenous tendons across joints in the skeleton. The transduction of chemical energy into mechanical work by muscle cells leads to muscle shortening and consequent movement. A high degree of specialization in this tissue is evident from the intricate architecture and kinetics of intra-cellular membrane systems, the contractile proteins, and the molecular components that transmit force extra-cellularly to the basement membrane and tendons. Muscle cells normally exhibit wide variations in activity level and are able to adapt in size, isoenzyme composition, membrane organization, and energetics. In pathologic states, they often become deconditioned. These examples of plasticity can be surprisingly swift and extensive. This chapter outlines the structure and function of muscle and its relationship to associated connective tissue. It also introduces the basis for the highly adaptive response to altered functional demands and diseases. Two excellent Web sites can be accessed for further information in these areas.[1,2]

## STRUCTURE

### Muscle Tissue

Parallel, aligned bundles of skeletal muscle fibers make up approximately 85% of muscle tissue and consist of a variety of signaling and contractile proteins (Table 5-1). Nerves, blood supply, and connective tissue structures that provide support, elasticity, and force transmission to the skeleton (see later discussion) constitute the remaining volume. Muscle fibers range in length from a few millimeters to 30 cm and in diameter from 10 to 500 μm, with a typical length of 3 cm and diameter of 100 μm. This elongated shape is determined by the organization of the contractile proteins that occupy most of the sarcoplasm. Each muscle has a limited range of shortening that is amplified into large motions by lever systems of the skeleton, usually operating at a mechanical disadvantage. Variations in geometric arrangements of the fibers—parallel, convergent (fan-shaped), pennate (feather-like), sphincter (circular), or fusiform (thick in the middle with tapered ends)—determine some of the mechanical properties. For example, a muscle with fibers aligned parallel to the force-generating axis will have more basic contractile units (i.e., sarcomeres, as discussed later) in series than a similarly sized pennate muscle, thus allowing the parallel muscle to contract more quickly, but with less force, than the pennate muscle. Muscles designed for strength (e.g., gastrocnemius) are typically pennate, whereas those designed for speed (e.g., biceps) tend to have parallel fibers. Muscles are commonly arranged around joints as antagonistic pairs facilitating bidirectional motion. When one muscle (the agonist) contracts, another (its antagonist) is relaxed and passively extended. Their roles reverse to actively generate the opposite motion, unless it occurs passively by the force of gravity.

An extensive network of areolar connective tissue, forming the endomysium, surrounds each muscle fiber. Fine nerve branches and small capillaries, which are necessary for the exchange of nutrients and metabolic waste products, penetrate this layer. The endomysium is continuous with the perimysium, a connective tissue network that ensheathes small parallel bundles of muscle fibers known as *fasciculi*, *intrafusal fibers*, *larger nerves*, and *blood vessels*. The epimysium encompasses the entire muscle. All three layers of connective tissue contain collagen—mostly types I, III, IV, and V—with types IV and V predominating in the basement membranes surrounding each skeletal muscle fiber. The

ATP, Adenosine triphosphate; ATPase, adenosine triphosphatase; SR, sarcoplasmic reticulum.

$\alpha1_2\alpha2$-chain composition of the collagen IV isoform is the most prevalent and provides the mechanical stability and flexibility of the basil lamina.[3,4] The perimysium and endomysium merge at the junction between muscle fibers and tendons, aponeuroses, and fasciae. These layers give the attachment sites great tensile strength and distribute axial force into shear forces over a larger surface area.

## Fiber Types

Muscles adapt to their specific functions. In any given muscle, part of this adaptation arises from its composition and organization of fiber types. Human skeletal muscle fibers can be classified according to their myosin heavy chain (MHC) isoform (I, IIA, or IIX). MHC molecules break down adenosine triphosphate (ATP) to produce the energy necessary for muscle contraction. The rate of ATP breakdown, or the adenosine triphosphatase (ATPase) rate, of the MHC isoforms is I < IIA < IIX, leading to contractions that are relatively slow in MHC I fibers, fast in MHC IIA fibers, and very fast in MHC IIX fibers. ATP synthesis primarily occurs through aerobic respiration (i.e., oxygen is required) in MHC I (slow oxidative) fibers. ATP synthesis is aided by the nature of MHC I fibers in that they have more mitochondria, an increased capillary blood supply, and more myoglobin compared with MHC IIX (fast glycolytic) fibers, which use anaerobic respiration (i.e., oxygen is not required) to restore their ATP levels. MHC I fibers produce less power than MHC IIX fibers but are more resistant to fatigue. MHC IIA (fast oxidative-glycolytic) fibers can use both aerobic and anaerobic respiration and fall in between I and IIX fibers in terms of mitochondria, blood supply, myoglobin, power output, and fatigability. Although most human skeletal muscles contain a mixture of fiber types, MHC I fibers are more prominent in muscles used for posture and endurance, and MHC IIX fibers dominate in muscles used for quick movements of short duration. Notably, individual fibers can contain a mixture of MHC isoforms, leading to six different fiber types in humans ("pure": MHC I, IIA, and IIX; "mixed": MHC I/IIA, IIA/IIX, and I/IIA/IIX), which allow for a wide range of contractile properties. A list of various attributes of MHC isoforms can be found in Table 5-2.

During development, fiber-type specificity may be partially determined before innervation.[5] Although the biologic events and signals responsible for designating functional specialization in muscle fibers are not fully understood, classic cross-innervation experiments demonstrated that innervation can dynamically specify and modify the type of muscle fiber.[6] After cross-innervation, the functional and histologic properties listed in Table 5-2 shift toward the target fiber type over a few weeks' time, indicating the ability of muscles to adapt and remodel in accordance with the pattern of neuronal activity.

**TABLE 5-2** Classification of Muscle Fiber Types by Myosin Heavy Chain Isoform

| General Features | MHC I | MHC IIA | MHC IIX |
|---|---|---|---|
| Mitochondria | Many | Intermediate | Few |
| Capillary blood supply | Extensive | Moderate | Moderate |
| SR membrane | Sparse | Extensive | Extensive |
| Z line | Wide | Moderate | Narrow |
| **Protein Isoforms** | | | |
| Myosin essential light chain | Slow and fast | Fast | Fast |
| Myosin regulatory light chain | Slow and fast | Fast | Fast |
| Myosin binding protein–C | Slow | Fast | Fast |
| Thin filament regulatory proteins | Slow | Fast | Fast |
| **Mechanical Properties** | | | |
| SR calcium ATPase rate | Slow | Fast | Fast |
| Actomyosin ATPase rate | Slow | Fast | Very fast |
| Contraction time | Slow | Fast | Very fast |
| Shortening velocity | Slow | Fast | Very fast |
| Power production | Low | Moderate | High |
| Resistance to fatigue | High | Moderate | Low |
| **Metabolic Profile** | | | |
| Oxidative capacity | High | Moderate | Low |
| Glycolytic capacity | Moderate | High | High |
| Glycogen | Low | High | High |
| Myoglobin | High | Moderate | Low |

ATPase, Adenosine triphosphatase; MHC, myosin heavy chain; SR, sarcoplasmic reticulum.

## EVENTS DURING MUSCLE CONTRACTION

### Neural Control

Voluntary control of muscle activation is a complex process. Afferent neurons emanating from sensory organs, such as cutaneous mechanoreceptors and thermoreceptors, pain receptors, joint receptors, and tendon organ and muscle spindles, provide the central nervous system (CNS) with stimuli in the form of action potentials that, with or without additional stimuli from the brain, provide the necessary information for feedback control of effector organs via efferent neurons.[7] Efferent neurons are specifically called *motor neurons* if their axons innervate muscle. Many times, more afferent than efferent neurons afford effective feedback control of movement and posture. The afferent and efferent neurons are accompanied by Schwann cells, which are glial cells residing in the peripheral nervous system.[8] Neurons are termed *myelinated* if Schwann cells wrap around the axon at regularly spaced intervals. The points of bare axon between these Schwann cells are called *nodes of Ranvier*. Myelination enhances the velocity of action potential propagation by compelling a saltatory conduction of the action potential between neighboring nodes. Schwann cells may also fully or nearly fully cover the axon, thus rendering the neuron unmyelinated and relatively slow in action potential propagation. Three groups of myelinated motor neurons (α, β, and γ) are distinguished by diameter, propagation velocity, and target fiber type. Skeletal muscle fibers typically are innervated at several neuromuscular junctions along their length by branches of an α motoneuron (the largest and fastest) or a β motoneuron (Figure 5-1). Muscle spindles are innervated by β or γ motoneurons, in addition to the afferent system, for sensing muscle length and force. A single motor neuron and the muscle fibers it innervates constitute a motor unit. When a motor neuron is excited, all fibers in the motor unit are triggered to contract simultaneously. A motor unit responsible for fine movement contains few muscle fibers, but motor units for gross movement generally contain many fibers. The level of muscle activation is controlled from the CNS by the number of motor units recruited and the stimulus rate.[9] Stimulus rate can be so infrequent as to elicit single muscle twitches, such as occur with the monosynaptic stretch reflex involving patellar tendon stretch and quadriceps activation, or conversely the stimulus rate can be so frequent that individual twitches effectively fuse, causing nearly continuous activation of muscle force.[10]

## Neuromuscular Transmission

At the neuromuscular junction, the axon tapers, loses its myelin sheath, and ends as a pre-synaptic terminal crowded with vesicles that contain the neurotransmitter acetylcholine. The postsynaptic membrane of the muscle is indented into folds that increase its surface area and the number of nicotinic acetylcholine receptors bound therein (see Figure 5-1). The junctional cleft is a 20 to 40 nm-wide space between the pre-synaptic and postsynaptic membranes.[11] When the motor neuron action potential reaches the pre-synaptic terminal, local voltage-gated $Ca^{2+}$ channels open and extra-cellular $Ca^{2+}$ streams into the terminal. Within milliseconds of $Ca^{2+}$ influx, the acetylcholine-loaded vesicles fuse with the pres-ynaptic membrane.[12] Exocytosed acetylcholine rapidly diffuses across the junctional cleft and binds to the nicotinic acetylcholine receptors, which in turn open $Na^+$ and $K^+$ channels of the postsynaptic membrane. The membrane is locally depolarized. An action potential is initiated and propagates along the muscle membrane (sarcolemma) at velocities up to 5 m/sec.

## Excitation-Contraction Coupling

A network of tubules invaginate the sarcolemma and run deep into the muscle fiber. This transverse tubule network (T-tubules) pervades the fiber at regular intervals, coinciding with sarcomere boundaries along the length of the muscle, and surrounds the contractile apparatus with connected longitudinal and lateral segments (Figure 5-2). The lumen of this network is open to the extra-cellular space and contains high $Na^+$ and low $K^+$ concentrations of interstitial fluid.[13] Action potentials at the surface membrane invade the entire T-tubular system. A specialized type of endoplasmic reticulum forms an entirely intra-cellular membrane system termed the *sarcoplasmic reticulum* (SR). Prevalent structures containing a T-tubule flanked by two terminal cisternae of the SR to form junctional complexes are termed *triads* (see Figure 5-2). Terminal cisternae contain oligomers of the $Ca^{2+}$-binding protein calsequestrin that provide the fiber with an internal reservoir of calcium ions. $Ca^{2+}$ channels, termed *dihydropyridine receptors* (DHPRs), are localized in the T-tubule membranes facing the cytoplasmic domain of SR $Ca^{2+}$ release channels, also called *ryanodine receptors* (RyRs), in the terminal cisternae membranes.[14] These membrane proteins are further characterized in Table 5-1.

When an action potential depolarizes the T-tubular membrane, the DHPRs, primarily voltage sensors in skeletal muscle, transfer a signal from the T-tubules to the RyRs by direct interprotein coupling. $Ca^{2+}$ is then released cooperatively through the RyRs from the SR into the myoplasm, where it activates the contractile machinery.[15] This sequence of events is termed *excitation-contraction coupling*.

Mutations in the α subunit of the DHPR in dysgenic mice lead to paralysis, because in these mutants, depolarization of the skeletal muscle membrane does not initiate release of $Ca^{2+}$ from the SR. Excitation-contraction coupling can be restored in cultured cells from these mice by transfection with complementary deoxyribonucleic acid (DNA) encoding for the DHPR,[16] and transfections using chimeric constructs[17] have pinpointed the domain within the DHPR that specifies skeletal- or cardiac-type excitation-contraction coupling.[18] Isoforms of the RyRs also help determine the characteristics of coupling between T-tubules and the SR.[19] Channelopathies in human skeletal and heart muscle have been linked to DHPR mutations.[20,21] Human malignant hyperthermia occurs in persons with mutant RyRs that become trapped in the open state after exposure to halothane anesthetic agents.[22]

## Contractile Apparatus

The specific locations and functions of the contractile proteins are listed in Table 5-1. Myofibrils (Figure 5-3D) are long, 1 μm diameter cylindrical organelles that contain the contractile protein arrays responsible for work production, generation of force, and shortening. Each myofibril is a column of sarcomeres, the basic contractile units, that are approximately 2.5 μm in length and are delimited by Z lines (Figure 5-3D and E) containing the densely packed structural protein α-actinin. The contractile and structural proteins within each sarcomere form a highly ordered, nearly

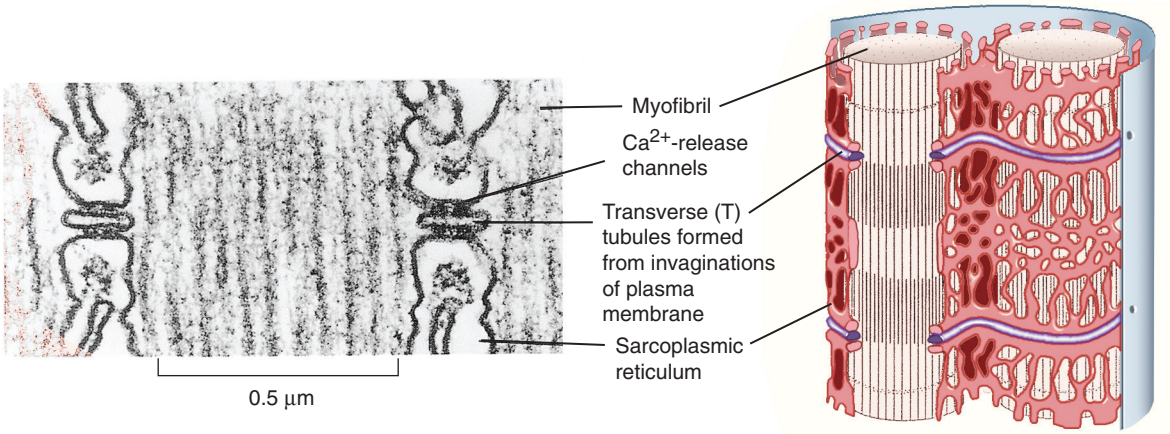

**Figure 5-2** Membrane systems that relay the excitation signal from the sarcolemma to the cell interior. In the electron micrograph, two T-tubules are cut in cross-section. Electron densities spanning the gap between T-tubules and sarcoplasmic reticulum membranes are the ryanodine receptors, which are channels that release calcium into the myoplasm. *(From Alberts B, Bray D, Lewish J, et al:* Molecular biology of the cell, *ed 2, New York, 1989, Garland Publishers. Micrograph courtesy Dr. Clara Franzini-Armstrong, University of Pennsylvania, Philadelphia.)*

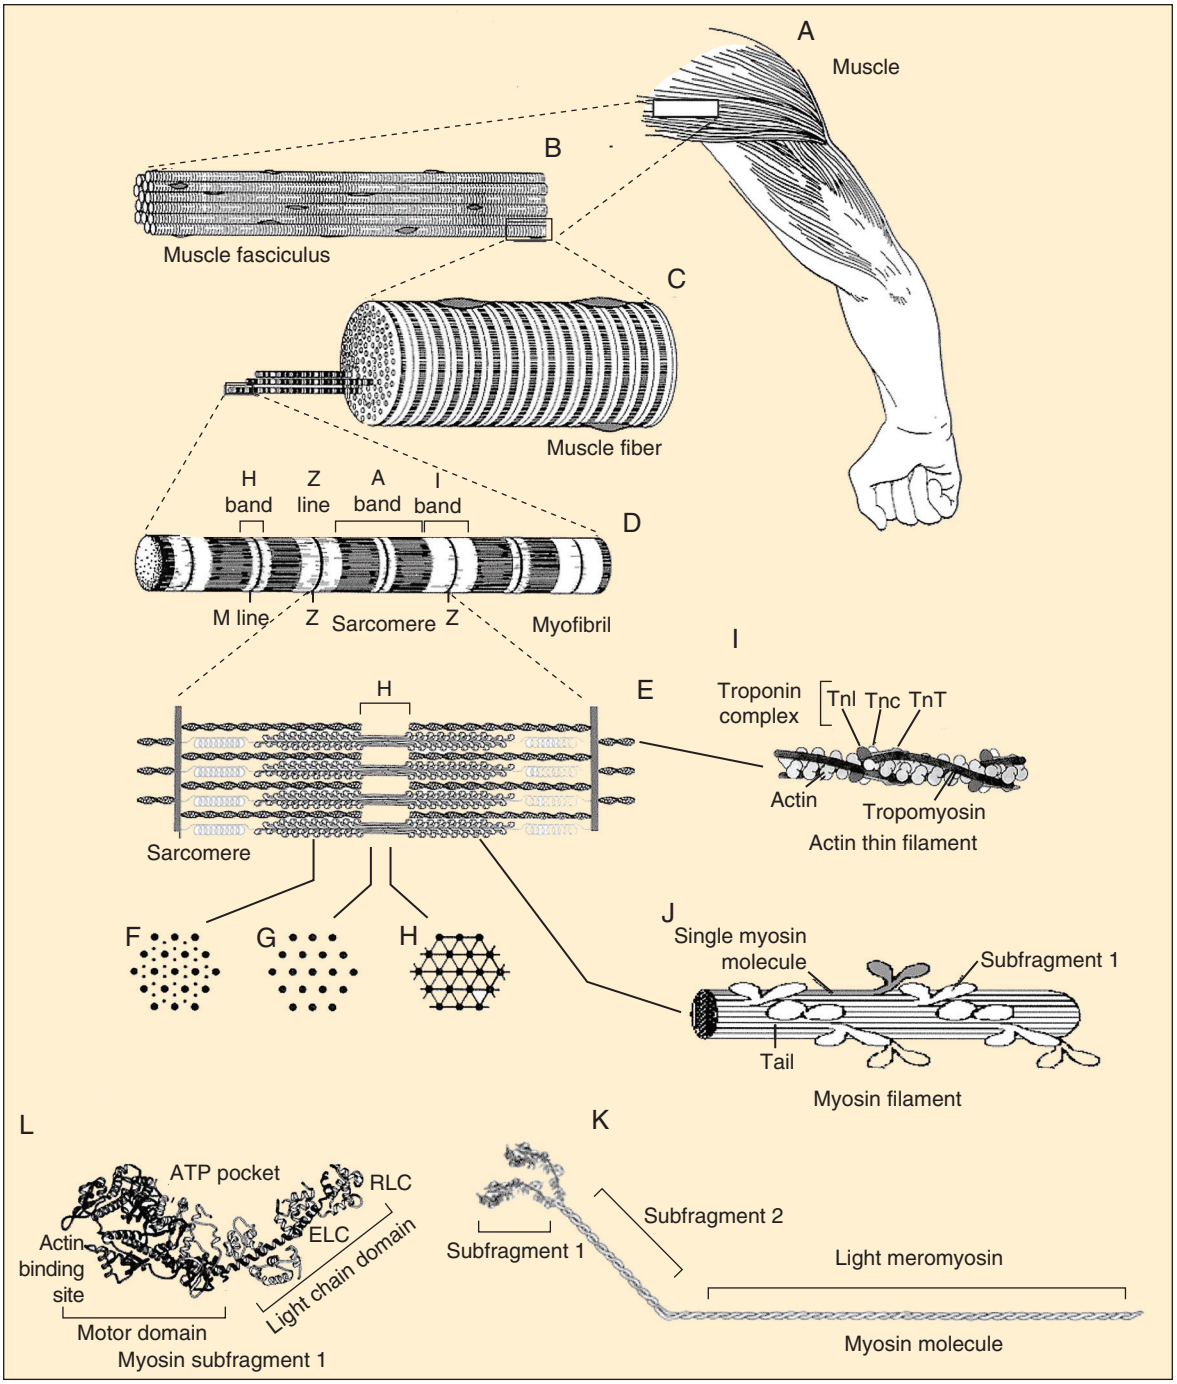

**Figure 5-3** Components of the contractile apparatus at successively increasing magnification from the whole muscle **(A)** to the molecular level (**I** through **L**). The myofibril **(D)** shows the banding pattern created by the lateral alignment of myofilaments (**I** and **J**) within the sarcomeres (**D** and **E**). Diagrams **F** to **H** show the cross-sectional structure of the filament lattice at various points within the sarcomere. Myosin is shown at the single two-headed molecule level **(K),** and the crystal structure of the globular motor domain is shown (**L** and subfragment 1) with the essential and regulatory light chains. ATP, Adenosine triphosphate; ELC, essential light chain; RLC, regulatory light chain. *(**A** through **K**, Modified from Bloom W, Fawcett DW: A textbook of histology, ed 11, Philadelphia 1986, WB Saunders; and **L** from Rayment I, Rypniewski WR, Schmidt-Base K, et al: Three-dimensional structure of myosin subfragment-1: a molecular motor.* Science *261:50–58, 1993.)*

crystalline lattice of interdigitating thick and thin myofilaments[23] (Figure 5-3E, I, and J). Myofilaments are remarkably uniform in both length and lateral registration, even during contraction,[24] resulting in the cross-striated histologic appearance of skeletal and cardiac muscles. This highly periodic organization has facilitated biophysical studies of muscle by sophisticated structural[23] and spectroscopic techniques.[25,26]

Thick filaments (1.6 μm long) that contain the motor protein myosin are located in the center of the sarcomere in the optically anisotropic A band (Figure 5-3D). These thick filaments are organized into a hexagonal lattice

stabilized by M protein[27] and muscle-specific creatine phosphokinase[28] in the M line (Figure 5-3D and E). Myosin (Figure 5-3K) is a highly asymmetric 470 kDa protein containing two 120 kDa globular $NH_2$-terminal heads, termed *cross-bridges* or *subfragment-1* (S1) (Figure 5-3L), and an α-helical coiled-coil rod, light meromyosin (Figure 5-3K). Two light chains, essential and regulatory, ranging from 15 to 22 kDa, are associated with the heavy chain in each S1 (Figure 5-3L). The rod portions of approximately 300 myosin molecules polymerize in a three-stranded helix to form the backbone of each thick filament (Figure 5-3J). The cross-bridges that protrude from these backbones contain ATPase and actin-binding sites responsible for the conversion of chemical energy into mechanical work. Besides their role in muscle contraction, at least 20 classes of nonmuscle myosins accomplish diverse tasks in cell motility such as chemotaxis, cytokinesis, pinocytosis, targeted vesicle transport, and signal transduction.[29] Thus myosin is the target for mutations, leading to a number of inherited muscle and neurologic diseases.[30,31]

Thin filaments (Figure 5-3I) are double-stranded helical polymers of actin that extend 1.1 μm from each side of the Z line and occupy the optically isotropic I band (Figure 5-3D and E). A regulatory complex containing one tropomyosin molecule and three troponin subunits (TnC, TnT, and TnI) is associated with each successive group of seven actin monomers along the thin filament (Figure 5-3I).[23] In the region where the thick and thin filaments overlap, the thin filaments are positioned within the hexagonal lattice equidistant from three thick filaments (Figure 5-3F). Both sets of filaments are polarized. In an active muscle, an interaction between the two filaments causes a concerted translation of the thin filaments toward the M line that shortens the sarcomere, and thus the muscle fiber and the entire muscle (Figure 5-3A through D). Actin is ubiquitous in the cytoskeleton of eukaryotic cells and, like myosin, fulfills many roles in determining cell shapes and motions.[32,33] Control of the actin cytoskeleton and diseases due to mutations in actin-binding proteins are being intensively investigated.[34]

Two of the largest identified muscle proteins, titin and nebulin, function in assembly and maintenance of the sarcomeric structure. Individual titin molecules (~3000 kDa) are associated with the thick filament and extend from the M line to the Z line.[35] Titin contains repeating fibronectin-like immunoglobulin and unusual proline-rich domains that confer molecular elasticity on the resting sarcomere.[36] Nebulin (~800 kDa) is associated with the Z line and thin filaments.[35] Protein connections from the contractile apparatus through the sarcolemma to the extra-cellular matrix are described later in this chapter. The cytoskeleton of muscle fibers also contains cytoplasmic actin, microtubules, and intermediate filaments.[37]

## Force Generation and Shortening

At rest, the thin filament regulatory proteins, troponin and tropomyosin, inhibit contraction (Figure 5-3I). During a twitch, $Ca^{2+}$ released from the SR binds to TnC, relieving this inhibition and thus allowing cross-bridges to attach to actin. A contraction results from cyclic interaction between actin and myosin (the cross-bridge cycle) that produces a relative sliding force between thin and thick filaments.[38] The energy source is the hydrolysis of ATP to adenosine diphosphate (ADP) and inorganic phosphate ($P_i$).

A simplified model of the chemomechanical events in the cross-bridge cycle is illustrated in Figure 5-4. Motor proteins, including myosin, can now be studied by

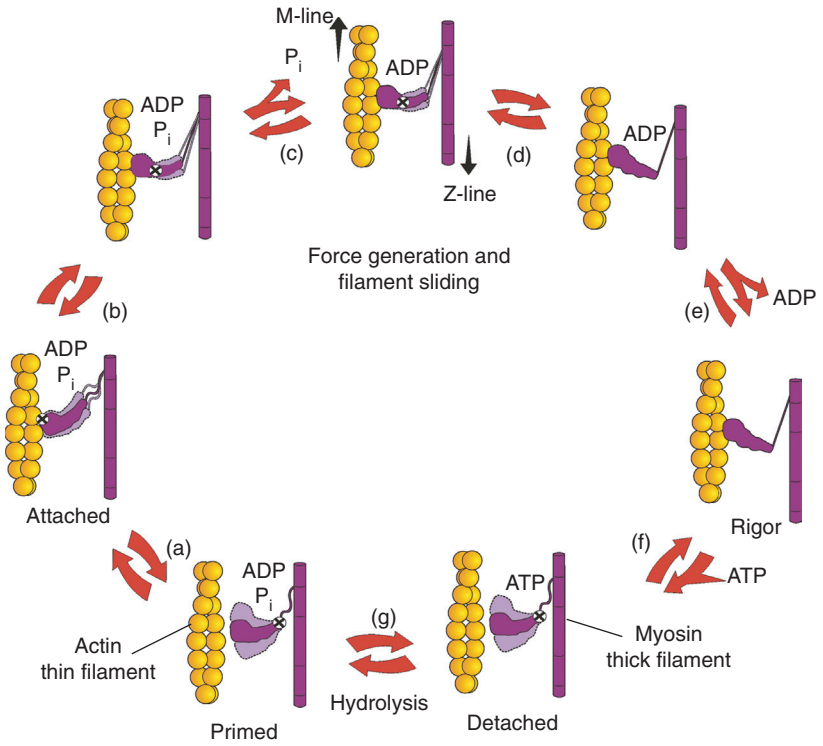

**Figure 5-4** The actomyosin cross-bridge cycle. Myosin molecules normally have two globular head regions (cross-bridges), but for clarity only one is shown. The ⊗ within the globular domain of myosin represents a hinge point with maximum flexibility. Each head binds with two actin monomers. The sequence of reactions consists of attachment (a); the force-generating transition (b); $P_i$ release (c); force generation and filament sliding (d); ADP release (e); ATP binding and detachment (f); and ATP hydrolysis (g). The *lighter shaded* heads near detached and force-generating myosin heads indicate mobility of cross-bridges in these states. ADP, Adenosine diphosphate; ATP, adenosine triphosphate; $P_i$, inorganic phosphate.

single-molecule biophysical techniques, which provide unprecedented detail on their dynamics.[39] When $Ca^{2+}$ is present, a complex of myosin, ADP, and $P_i$ attaches to the thin filament (step a), and structural change within the myosin S1 initiates force production and the release of $P_i$ (steps b and c).[40,41] The conformational change in the cross-bridge that leads to generation of force is a tilting motion of the light chain region.[42,43] Filament sliding that leads to shortening of the sarcomere occurs during a strain-dependent transition between two ADP states (step d). After ADP is released (step e), ATP binds to the active site and dissociates myosin from actin (step f). Myosin then hydrolyzes ATP (step g) to form the ternary myosin–ADP-$P_i$ complex, which can reattach to actin for the next cycle.

If the mechanical load on the muscle is high, the contractile apparatus produces a force without changing length (an isometric contraction). If the load is moderate, the thin filaments slide actively toward the center of the sarcomere, resulting in shortening of the entire muscle. The width of the muscle increases during shortening, so the volume stays constant. Work production (concomitant force and sliding) is associated with an increase in the ATPase rate. Thermodynamic efficiency (mechanical power divided by energy liberated by ATPase activity) approaches 50%—a remarkable figure given that manufactured combustion engines seldom achieve efficiencies greater than 20%.

### Relaxation

The twitch is terminated by reversal of all steps in the activation. $Ca^{2+}$ released from the SR is taken up again by $Ca^{2+}$-ATPase pumps located in longitudinal membranes of the SR. The myoplasmic $Ca^{2+}$ concentration then decreases, and $Ca^{2+}$ dissociates from TnC, deactivating the thin filament. When the number of attached cross-bridges declines below a certain threshold, tropomyosin inhibits further cross-bridge attachment, and tension declines to the resting level. $Ca^{2+}$ diffuses within the longitudinal SR to calsequestrin sites in the terminal cisternae, ready to be released in the next twitch. Myosin continues to hydrolyze ATP at a low rate in relaxed muscle, accounting for a sizable proportion of basal metabolism.

## TRANSMISSION OF FORCE TO THE EXTERIOR

### Cell-Matrix Adhesions

The muscle cell is closely connected to the basal lamina along its entire surface. Several transmembrane macromolecular complexes link the myofibrils and actin cytoskeleton to laminins and collagen in the extra-cellular matrix. Attachment complexes for muscle, analogous to the focal adhesions of motile and epithelial cells and to the adhesion plaques and intercalated disks in cardiac muscle, contain filamentous actin, vinculin, talin, and integrin (primarily the α7β1 isoform), which is the transmembrane link to laminin (Figure 5-5). In muscle, the main laminin isoforms are laminin-2 (α2β1γ1) and laminin-4 (α2β2γ1), which collectively are termed *merosin*. In addition to providing mechanical coupling between the cytoskeleton and the extra-cellular matrix, the laminin-integrin system may

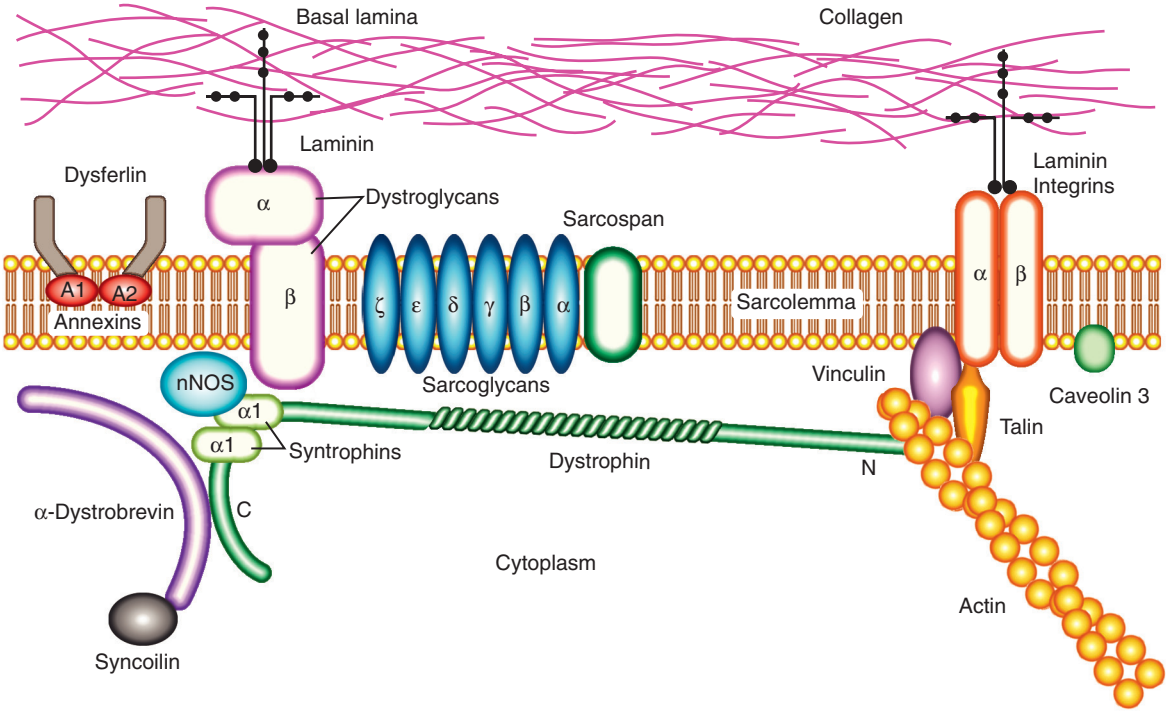

**Figure 5-5** Connections between the muscle cytoskeleton and the extra-cellular matrix. Actin is linked through integrins to the matrix, as in many cell types. Dystrophin forms an extra link through the dystroglycan-sarcoglycan complex of glycosylated proteins. The helical section of dystrophin is homologous to spectrin and may form homodimers or oligomers. Dystrophin links two intricate systems linking the sarcolemma to the basal lamina. The carboxy (COOH)-terminus of dystrophin is associated with the sarcoglycans, dystroglycans, dystrobrevin, syncoilin, neuronal nitric oxide synthase (nNOS), and the syntrophins. The $NH_3$-terminus links actin, vinculin, and the integrins with laminin and the basil lamina. These two adhesion systems provide a supportive substructure to maintain the integrity of the sarcolemma. The annexins and dysferlin have a role in muscle regeneration.

**TABLE 5-3** Classification of Muscular Dystrophies

| Disease | Genetic Locus | Inheritance | Protein | Outcome |
|---|---|---|---|---|
| Duchenne/Becker | | XR | Dystrophin | Lethal |
| Emery-Dreifuss | | XR | Emerin, lamins A and C | 40% lethality |
| **Limb-Girdle Muscular Dystrophies** | | | | |
| LGMD 1A | 5q31 | AD | Myotilin | With LGMD, less-severe forms can emerge during the first three decades, leading to loss of ambulation after 30 yr of age; the most severe forms start at 3-5 yr of age and progress rapidly |
| LGMD 1B | 1q11-q21 | AD | Laminin A/C | |
| LGMD 1C | 3p35 | AD | Caveolin | |
| LGMD 1D | 6q23 | AD | — | |
| LGMD 1E | 7q | AD | — | |
| LGMD 1F | 7q32 | AD | — | |
| LGMD 1G | 4p21 | AD | — | |
| LGMD 2A | 15q15.1-q21.1 | AR | Calpain 3 | |
| LGMD 2B | 2p13 | AR | Dysferlin | |
| LGMD 2C | 13q12 | AR | γ-Sarcoglycan | |
| LGMD 2D | 17q12-q21.33 | AR | α-Sarcoglycan | |
| LGMD 2E | 4q12 | AR | β-Sarcoglycan | |
| LGMD 2F | 5q33-q34 | AR | δ-Sarcoglycan | |
| LGMD 2G | 17q11-q12 | AR | Telethonin | |
| LGMD 2H | 9q31-q34.1 | AR | E3-Ubiquitin ligase (TRIM32) | |
| LGMD 2I | 19q13.3 | AR | Fukutin-related protein | |
| LGMD 2J | 2q24.3 | AR | Titin | |
| LGMD 2K | 9q34 | AR | Protein O-mannosyltransferase | |
| **CMDs with CNS Involvement** | | | | |
| Fukuyama CMD | 9q31 | AR | Fukutin | LE, 11–16 yr |
| Walker-Warburg CMD | 1p32 | AR | O-Mannosyltransferase | LE, <3 yr |
| Muscle-eye-brain CMD | 1p32-34 | AR | O-MNAGAT | LE, 10–30 yr |
| **CMDs without CNS Involvement** | | | | |
| Merosin-deficient classic type | 6q2 | AR | Merosin (laminin $A_2$) | Many patients never walk; others have an LGMD pattern |
| Merosin-positive classic type | 4p16.3 | AR | Selenoprotein N1, collagen VI $\alpha_2$ | Course stabilizes in late childhood; many continue to walk into adulthood |
| Integrin-deficient CMD | 12q13 | AR | Integrin α7 | Presents early in infancy with hypotonia and delayed milestones |
| **Other Dystrophies** | | | | |
| Facioscapulohumeral | 4q35 | AD | — | 20% wheelchair bound |
| Oculopharyngeal | 14q11.2-q13 | AD/AR | Polyadenylate binding protein nuclear 1 | Onset: ~48 yr, 100% symptomatic by age 70 yr |
| Myotonic dystrophy | 19q13.3 | AD | DMPK, CCHC-type zinc finger and CNBP | Onset: 50% show signs by age 20 yr; variable severity |

AD, Autosomal dominant; AR, autosomal recessive; CCHC, cysteine and histidine amino acid sequence in this class of zinc finger; CMD, congenital muscular dystrophy; CNBP, cellular nucleic acid–binding protein; CNS, central nervous system; DMPK, dystrophia myotonica-protein kinase; LE, life expectancy; LGMD, limb-girdle muscular dystrophy; O-MNAGAT, O-mannose β-1,2-*N*-acetylglucosaminyl transferase; XR, X chromosome–related.

provide a signaling pathway to regulate localized protein expression.[44] Defects in the expression of many of the cytoskeletal proteins lead to various forms of muscular dystrophy, as summarized in Table 5-3.[45]

A specialized linkage between the cytoskeleton and the basal lamina in muscle, complementary to the integrin focal adhesion system, is the dystrophin-glycoprotein complex (see Figure 5-5). Dystrophin, a 427 kDa peripheral cytoskeletal protein, has been postulated to function as a mechanical link between the cytoskeleton and the cell membrane or as a shock absorber, or to contribute mechanical strength to the membrane. Its absence or truncation causes Duchenne and Becker muscular dystrophies.[46] The N-terminus of dystrophin binds to actin via a region with sequence homology to the actin-binding domain of α-actinin. This end of the dystrophin molecule may be linked to the basal lamina via the same proteins described previously for focal adhesion-like complexes (see Figure 5-5). The C-terminus binds to a transmembrane dystroglycan-sarcoglycan complex, which in turn binds to the laminins. Muscular dystrophies of varied severity are associated with loss of these components (see Table 5-3).[47] Dystroglycans are also required for early embryonic development of muscle, possibly organizing laminin localization and assembly.[48,49] Utrophin, a smaller dystrophin-related protein (395 kDa), may also link the actin cytoskeleton to the dystroglycans, especially near the neuromuscular junction and in nonmuscle cells. Overexpression of this protein or truncated dystrophin constructs are promising avenues for gene therapy in persons with Duchenne muscular dystrophy.[50] The unusual intricacy of cell-matrix connection systems in muscle may relate to the high forces generated during contraction.

## Myotendinous Junction

The force of muscle contraction is transmitted to the skeleton via the tendons, which are composed of collagens type I and III, blood vessels, lymphatic ducts, and fibroblasts. At

the ends of the muscle fibers, myofibrils are separated by invaginations of sarcolemma filled with long bundles of collagen arising from the tendon. These membrane folds increase the surface area for bearing the mechanical load by approximately 30-fold. Instead of terminating in the Z disks, actin filaments insert into a subsarcolemmal matrix containing α-actinin, vinculin, talin, and integrin. The force is transmitted through laminin to the collagen of the tendon.

## ENERGETICS

Metabolic pathways in muscle cells are specialized for the variable and at times extreme rates of ATP splitting by the contractile apparatus and membrane ionic pumps. Among the dozens of metabolic enzymes present, only the most important ones with regard to normal muscle function are mentioned here.

### Buffering of Adenosine Triphosphate Concentration

The ATP content (~5 mM) is sufficient for only a few seconds of contraction, and thus rapid and effective buffering of ATP during contraction is essential for the maintenance of activity. ADP formed by the hydrolysis of ATP is rephosphorylated by transfer of a phosphate group from creatine phosphate (20 mM in a resting cell) by creatine phosphokinase located within the M line of the sarcomere, in the myoplasm, and between the inner and outer membranes of the mitochondria. Adenylate kinase, known in muscle as *myokinase*, catalyzes the transfer of a phosphate group between two ADP molecules, forming ATP and adenosine monophosphate (AMP). The by-products of the rapid enzymatic reactions that maintain ATP concentration are therefore creatine, $P_i$, and AMP. Some of the AMP is converted to inosine monophosphate by adenylate deaminase. A creatine phosphate shuttle has been proposed to enhance energy flux.[51] According to this hypothesis, creatine phosphate is split within the contractile apparatus and creatine is predominantly rephosphorylated in the mitochondria.

### Glycolysis

Muscles use some combination of glucose and fatty acids (and ketone bodies in some situations) as fuel, depending on their metabolic state (fasted vs. fed) and activity status (rested vs. exercise). The muscle compartment contains most of the body storage of glycogen, which is converted to glucose-6-phosphate for local use. Muscle fibers lack glucose-6-phosphatase and thus do not export glucose. During intense activity, especially in anaerobic conditions, the rate of glycolysis and the production of pyruvate exceed the rate of pyruvate consumption by the citric acid cycle. Excess pyruvate is reduced to lactate by lactate dehydrogenase, which has tissue-specific isoforms. The lactate-dehydrogenase reaction also produces nicotinamide adenine dinucleotide ($NAD^+$), which is necessary for glycolysis, but otherwise lactate is not useful within the muscle. Lactate is freely permeable through the sarcolemma, and a local increase in the extra-cellular lactate concentration or acidification produces exertional pain ("the burn"). Lactate is transported through the blood to the liver, where it is converted back to pyruvate and then to glucose, which is released into the blood for use by other tissues, such as muscle and brain. This sequence of steps, termed the *Cori cycle*, transfers some of the high metabolic load to the liver and "buys time" until oxidative metabolism is available.

### Oxidative Phosphorylation

In aerobic conditions, pyruvate enters the mitochondria, where it is converted to acetyl-coenzyme A (CoA). Acetyl-CoA can enter the tricarboxylic acid cycle, where it is oxidized to carbon dioxide and water, generating reduced NAD (NADH). Fatty acids also contribute to the mitochondrial acetyl-CoA pool through the process of beta-oxidation. The reducing equivalents NADH and reduced form of flavin adenine dinucleotide ($FADH_2$) are subsequently oxidized by the electron transport chain, and an $H^+$ gradient is established across the mitochondrial membrane. This gradient is used to catalyze the phosphorylation of ADP to ATP by the mitochondrial ATP synthase. For example, when glycolysis and oxidative phosphorylation are combined, up to 38 ATP molecules can be generated by the oxidation of each molecule of glucose. This process is energetically much more favorable than the production of lactate, but it can occur only when molecular oxygen is available. Myoglobin is an iron-heme complex protein that facilitates oxygen transport within muscle cells. Tissue hydrostatic pressure in a contracting muscle often exceeds arterial perfusion pressure, so the strongest contractions are anaerobic. The content of oxidative enzymes, myoglobin, and mitochondria determines the predominant type of energy metabolism and varies in different muscle types, as was discussed previously (see Table 5-2).

## FATIGUE AND RECOVERY

During intense or prolonged activity, muscle fatigue is caused by alterations of metabolite levels that suppress the generation of force at the contractile apparatus, during excitation-contraction coupling, or both.[52] Markedly increased myoplasmic $P_i$ and $H^+$ concentrations and decreased creatine phosphate levels have been detected by magnetic resonance spectroscopy.[53] When the creatine phosphate level declines, maintained activity depends on glycogenolysis until glycogen stores are depleted. During prolonged intense activity, the respiratory and circulatory systems are unable to meet the oxygen demands of the tissue. Production of force declines well before the ATP concentration is compromised.

The chemomechanical link between $P_i$ release and the generation of force (see Figure 5-4) implies that increased myoplasmic $P_i$ in fatigued muscle reduces the magnitude of force simply by mass action.[40] Decreased pH in the muscle, caused in part by accumulation of lactate, and insufficient availability of acetylcholine at the neuromuscular junction, leading to failure of synaptic transmission, also contribute to decreased work production. Because the respiratory and circulatory systems do not supply sufficient oxygen to support metabolism during intense activity, an oxygen debt is incurred. Blood flow and oxygen uptake continue at an enhanced level after the period of exercise to reclaim this

energy. Rephosphorylation of creatine can take place within a few minutes, but glycogen resynthesis requires several hours. Recovery processes also involve restoration of ionic gradients across membrane-bound compartments and require consumption of further energy.

## PLASTICITY

The strength and endurance of a muscle are altered dramatically within weeks after changes in the demands for its use, its mobility, or its hormonal or metabolic environment. The effects of this adaptive response should be considered in any clinical situation that causes a substantial shift in these factors and with regard to the long-term quality of life of the patient.

### Adaptation to Muscle Use/Disuse

Muscle is a use-dependent tissue, meaning that its functional characteristics are closely tied to the number and type of activity patterns that it experiences. Increased muscle use through physical exercise leads to adaptations in muscle fibers that include alterations in specific contractile, regulatory, structural, and metabolic proteins, as well as changes in neural recruitment patterns. The type (aerobic vs. resistance), frequency, intensity, and duration of a training stimulus and the external load influence the adaptive response.[54] Resistance training causes cross-sectional hypertrophy of primarily fast type II fibers (see Table 5-2) by increasing the size of existing fibers without inducing hyperplasia. This hypertrophy is driven primarily by increased myofilament protein, which occupies the vast majority of fiber volume (~80%), but other myocellular components (e.g., mitochondria) are also increased so as to maintain the relative volume fraction of each cellular component constant with hypertrophy. Aerobic training, on the other hand, enhances the oxidative capacity and volume density of mitochondria in oxidative type I and IIA fibers and generally does not induce hypertrophy. In this context, resistance training can be seen as altering function by increasing the overall quantity of the muscle, whereas aerobic training alters the functional quality of the muscle to elicit greater endurance to repetitive contraction.

When physical activity is reduced—for instance, with bed rest during hospitalization—the cross-section of the fibers decreases, causing muscle weakness, and endurance is reduced. Of note, these changes are worsened when accompanied by acute and chronic disease,[55] to the extent that up to 10% of muscle protein content can be lost per week.[56] After significant periods of muscle disuse, loss of muscle strength and endurance can progress to the point at which patients are unable to accomplish simple activities of daily living. Although younger, healthy persons tend to regain muscle size and function readily with exercise rehabilitation, the extent to which older persons and those with chronic disease can recover from muscle disuse appears to be impaired.

### Hormonal Control

Hormones, acting in an endocrine or paracrine-autocrine fashion, also have the capacity to alter muscle structure and function. The most prominent hormonal controller of muscle is insulin, which regulates muscle anabolism in response to feeding by suppressing protein breakdown and facilitating protein synthesis via stimulation of amino acid uptake into muscle. In addition to insulin, insulin-like growth factor-I, which largely mediates the effects of growth hormone on muscle, stimulates the hypertrophy of existing muscle fibers by stimulating muscle protein synthesis and inhibiting protein breakdown, and it may contribute to muscle growth/regeneration through effects on muscle satellite cells.[57,58] In men, testosterone has clear anabolic effects on muscle, and conditions that reduce circulating testosterone levels lead to muscle atrophy and weakness. The role of testosterone in women is less certain. Estrogen in women is widely believed to have effects on muscle size and strength, although experimental evidence to support this contention is lacking, and the effects of estrogen on other metabolic processes in muscle appear to be relatively minor at concentrations observed during normal menstrual cycles and in the post-menopausal period.

In many acute and chronic illnesses, changes in the hormonal milieu can affect muscle. The most predominant factors thought to elicit these changes are cytokines and other inflammatory modulators,[59] although alterations in classic stress hormones, such as cortisol and glucagon,[60] also contribute to muscle catabolism. In most cases, the effect of these catabolic hormones is to direct amino acid substrates toward the liver to necessarily support the acute phase protein response. In addition, the type of persistent low-grade inflammation that occurs with aging and in many chronic diseases may have similar detrimental effects on muscle when compounded over extended periods. Whether modulation of these catabolic hormonal factors has beneficial effects in maintaining muscle size and functionality under physiologic and pathophysiologic conditions, however, is not certain.

## AGING

*Sarcopenia*, defined as loss of skeletal muscle mass and function with age, manifests as an inability to perform simple tasks of everyday life and contributes to disability, a greater risk for falls and fractures, an increase in all-cause mortality, and, in general, a poor quality of life. Healthy persons exhibit approximately a 30% decrease in total muscle mass between the ages of 30 and 80 years. Although it is universally accepted that whole muscle force production is reduced with age,[61-64] disagreement exists about whether this effect is due solely to reduction in muscle mass or if loss of force production per unit muscle size is also a factor. Most single-fiber studies that have measured isometric force production per unit fiber cross-sectional area (i.e., accounting for age-related reductions in muscle size) show that aging decreases force-producing capabilities.[65-72] In addition, whole muscle[61,62,73-75] and single fiber[65,67-69,71,72,76] studies typically find decreases in contractile velocity with age, and this decrease leads to further reduction in the muscle performance of elderly persons, especially for movements requiring high-velocity contractions. Altogether, these results suggest that aging alters the fundamental contractile properties of skeletal muscle fibers, which decrease, at least in part, whole muscle performance. Age-related changes in

motor unit recruitment, activation of agonist and antagonist muscles, and fibrosis can exacerbate single fiber changes and further reduce whole muscle performance.

## CONCLUSION

The complex functional capacity of muscle to produce finely tuned and coordinated movements is ultimately expressed as the transduction of chemical to mechanical energy by actomyosin. A twitch is initiated by the following mechanisms: an action potential propagated from the CNS along an α motoneuron, neuromuscular chemical transmission, direct protein–protein communication at the T-tubule–sarcoplasmic reticulum junction, $Ca^{2+}$ diffusion in the myoplasm, and $Ca^{2+}$ binding to thin filament regulatory proteins. Because the CNS controls activity through recruitment of motor units, gradation and coordination of movement depend critically on the pattern of connections between α motoneurons and muscle fibers and on variations of properties among motor units. Development, maintenance, and aging of the muscular system involve a complex series of genetic programs and cellular interactions that are beginning to be understood at the molecular level. Adaptation of motor unit properties is evident not only in training regimens but also in reduced activity caused by pain or joint immobilization and in compromised metabolic, hormonal, or nutritional conditions. Hence the plasticity of muscle influences the clinical course of many diseases. In addition to its importance in pathophysiology, muscle serves as an excellent substrate for understanding the molecular basis of cell development, protein structure-function relationships, cell signaling, and energy transduction processes.

CHAPTER 6

# Biomechanics

Kenton Kaufman • KaiNan An

**KEY POINTS**

**Kinematics is the study of the geometric and time-dependent aspects of motion without analyzing the forces causing the motion.**

**The general unconstrained movement in three-dimensional space requires the description of three translations and three rotations to fully describe joint motion.**

**Kinetics is the study of the forces that cause motion of a rigid body. These forces can be classified as either external forces or internal forces.**

**External forces represent the action of objects contacting the body, gravitational forces, or force due to inertia of the body.**

**Internal forces are the body's responses to external forces, which consist of muscle, ligament, and joint contact forces.**

**Because of the relatively smaller mechanical advantages, large muscle and tendon forces and thus internal joint forces are expected when performing any activities.**

**The anatomic structure responsible for joint constraint can be divided into passive and active elements. Passive elements, consisting of the capsulo-ligamentous structures and bony articulating surfaces, provide the static constraints of the joint. The active elements include muscle-tendon units, which provide dynamic joint constraints.**

Biomechanics combines the field of engineering mechanics with the fields of biology and physiology. Biomechanics applies mechanical principles to the human body in order to understand the mechanical influences on bone and joint health. Forces that load the joints are generated by muscles and transmitted by tendons. Bones must withstand these forces. Developments in the field of biomechanics have improved our understanding of normal and pathologic gait, mechanics of neuromuscular control, and mechanics of growth and form. This knowledge has contributed to the development of medical diagnostic and treatment procedures. It has provided the basis for the design and manufacture of medical implants and orthotic devices and has enhanced rehabilitation therapy practices. Biomechanics has also been used to improve human performance in the workplace and in athletic competition.

Mechanics is a branch of physics that is concerned with the motion and deformation of bodies that are acted on by mechanical forces. Mechanics is one of the oldest physical sciences, dating back to Aristotle (384-322 BC), who conducted an organized analytical analysis of animal movement. Leonardo da Vinci (1452-1519) investigated the mechanics of the human body, and his detailed anatomic sketches represent the birth of anatomy as a discipline and of mechanics as the science governing human motion. Although da Vinci wrote extensively on body mechanics, the man generally credited to be the father of modern biomechanics is Giovanni Alphoso Borelli (1608-1679). His book *De Motu Animalian* provided a quantitative graphical solution to a musculoskeletal biomechanics problem (Figure 6-1).[1]

Engineering mechanics is the discipline devoted to the solution of mechanical problems through the integrated application of mathematical, scientific, and engineering principles. With roots in physics and mathematics, engineering mechanics is the basis of all engineering mechanical sciences. Engineering mechanics is an applied mechanics branch of the physical sciences. The broad field of applied mechanics can be further divided into three main parts: rigid body mechanics, deformable body mechanics, and fluid mechanics. In general, a material can be characterized as either a solid or fluid. Solid materials can be considered to be rigid or deformable. A rigid body is one that cannot be deformed. In reality, every object undergoes deformation to some extent when acted upon by external forces. However, this is a definition of convenience that is used to simplify complex problems. For example, during the study of movement in gait analysis, the bones are considered to be rigid bodies when compared with the soft tissues joining the bones. External loads applied to a rigid body result in internal loads, stresses, and deformations. The mechanics of deformable bodies deal with the relationships between externally applied loads and their internal effects. The mechanics of deformable bodies have strong ties with the field of materials science and are more complex when compared with the analyses required in rigid body mechanics. The purpose of this chapter is to give you only a brief idea of biomechanics. We will focus on rigid body mechanics.

Basic biomechanics relies heavily on Newtonian mechanics. These laws were introduced by Sir Isaac Newton and form the basis for analyses in statics and dynamics. Statics analyzes the forces that occur in rigid bodies that are in static equilibrium. Dynamics is the study of bodies in motion. The general field of dynamics consists of two major areas: kinematics and kinetics. Ultimately, proper joint constraint and stability enables limb function in characteristic ways.

## KINEMATICS

Kinematics is the study of the geometric and time-dependent aspects of motion without analyzing the forces causing the

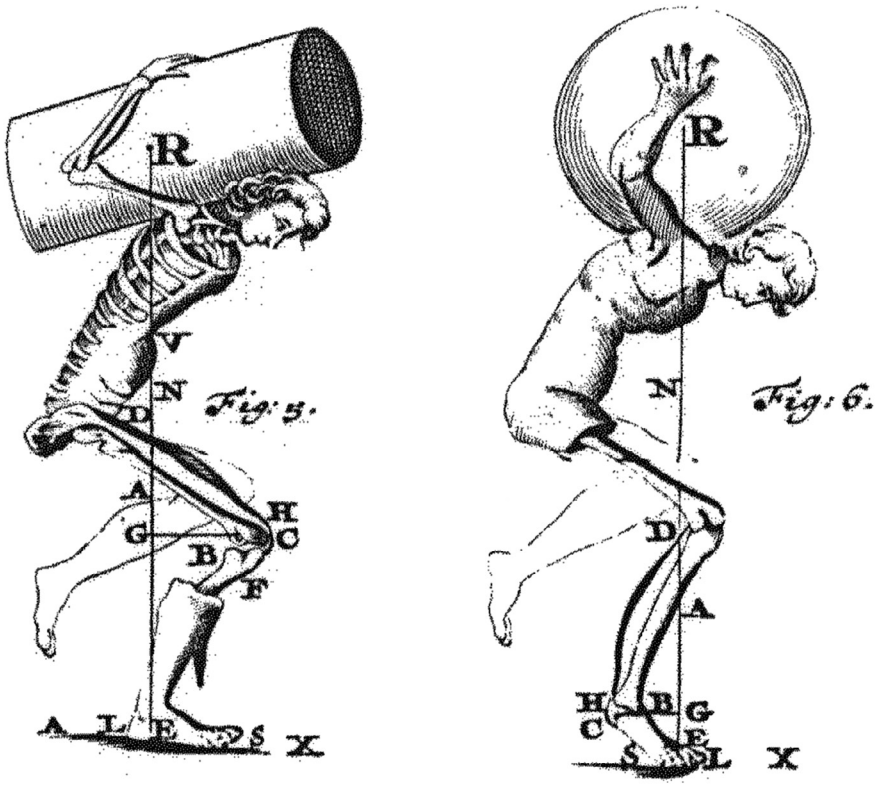

**Figure 6-1** Borelli's quantitative graphical solution to a musculoskeletal biomechanics problem. *(From Borelli GA:* De motu anumalium, *Batavis, 1685, Lugduni.)*

motion. Kinematic analysis is used to relate displacement, velocity, acceleration, and time. To study kinematics in an organized manner, it is common to classify the motion as translational, rotational, or general. Translational motion occurs when a straight line drawn between two points on the body remains in the same direction during the motion. Translational motion can be either rectilinear motion (if the paths are straight lines) or curvilinear (if the paths are curved lines). Rotational motion occurs when the points on the body move in a circular path around an axis of rotation. The angular motion occurs about a central line known as the *axis of rotation*, which lies perpendicular to the plane of motion. The third class of motion is called *general motion*, or *displacement*, which occurs if a body undergoes both translational and rotational motion simultaneously.

Kinematics can be analyzed in two-dimensional (2-D) or three-dimensional (3-D) space. When all points of a rigid body move parallel to a plane, the motion is referred to as *planar motion*, which can be thought of as 2-D motion. The more general type of rigid body motion is 3-D motion. Six independent parameters are required to describe 3-D motion. These parameters are called *degrees of freedom*, or the number of independent coordinates in a coordinate system that is required to completely specify the position of an object in space. A rigid body in space has a maximum of six degrees of freedom, consisting of three translations (expressed by linear coordinates) and three rotations (expressed by angular coordinates). The general movement of an object is defined by a vector quantity that is a combination of both linear and angular displacement. Velocity is the time-related change of displacement. Linear velocity is expressed in units of length per time (e.g., m/sec). Angular velocity is expressed in units of angular measure per time (e.g., rad/sec). Because velocities reflect vector quantities, both magnitude and direction must be specified. Acceleration is the time-rate of change of velocity. Linear acceleration is expressed in units of length per time squared (e.g., $m/sec^2$). Angular acceleration is the time rate of change in angular velocity (e.g., $rad/sec^2$). Accelerations are also vector quantities, and both magnitude and direction must be specified.

Kinematic techniques have been used to study body movements in both 2-D and 3-D space. The human body is typically modeled as a number of interconnected rigid body segments (Figure 6-2). A coordinate system is affixed to each rigid body segment to establish an anatomic coordinate system. External markers are used to define orthogonal coordinate systems whose axes define the position of these body segments. Joint motion is then described as the relative motion of the distal body segment with respect to the proximal body segment. Limb segments are assumed to undergo angular displacement during human movement. However, more sophisticated analyses will also quantify the linear displacement that limb segments may undergo. These measures of relative segmental angles have been used to describe human walking and other activities of daily living.[2-7]

For example, knee motion in the sagittal plane can be characterized throughout the gait cycle (Figure 6-3). At heel strike, the knee is nearly fully extended (with knee

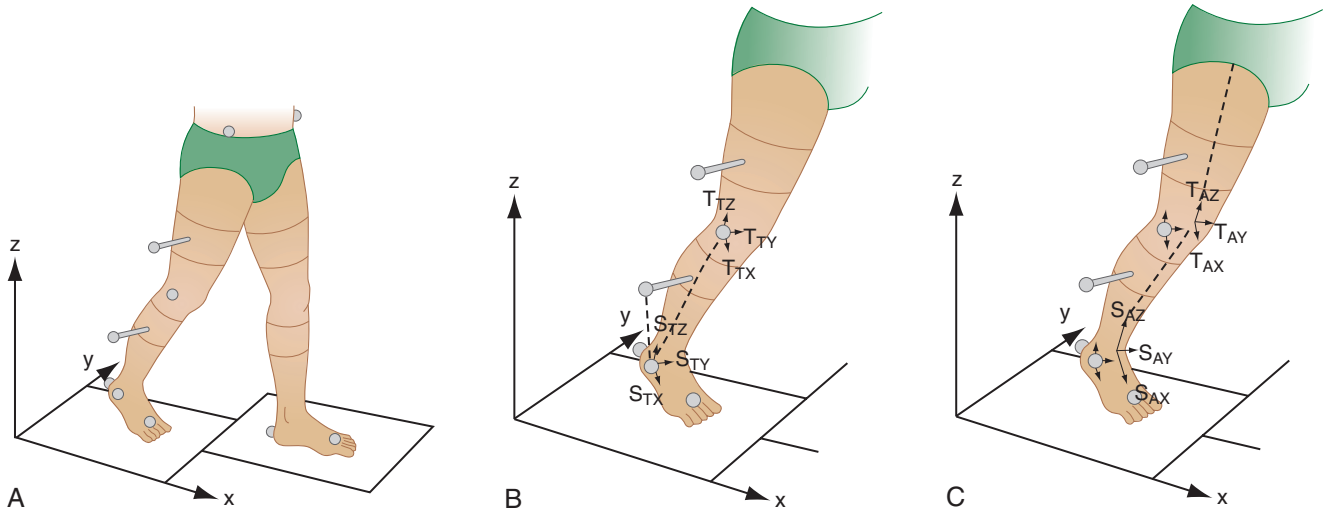

**Figure 6-2** The kinematic technique used to study body movement in three-dimensional space. Body-fixed reflective markers are used to establish anatomic coordinate systems. **A,** Video camera measurement systems calculate the location of external markers placed on the body segments and aligned with specific bony landmarks. **B,** A body-fixed external coordinate system is then computed from three or more markers on each body segment. Body-fixed external coordinate systems are shown for the thigh ($T_T$) and shank ($S_T$). The coordinate system is shown for the three orthogonal directions (e.g., x, y, and z). The body-fixed thigh coordinate system is designated $T_{Tx}$, $T_{Ty}$, and $T_{Tz}$. **C,** Using a subject-specific calibration relates the external coordinate system with an anatomic coordinate system through the identification of anatomic landmarks (e.g., the medial and lateral femoral condyles and medial lateral malleoli). The anatomic coordinate system for the thigh is then designated $T_{Ax}$, $T_{Ay}$, and $T_{Az}$. *(From Kaufman KR: Objective assessment of posture and gait. In Bronstein AM, Brandt T, Marjorie H, editors:* Clinical disorders of balance, posture, and gait, *Oxford, England, 2004, A Hodder Arnold Publication.)*

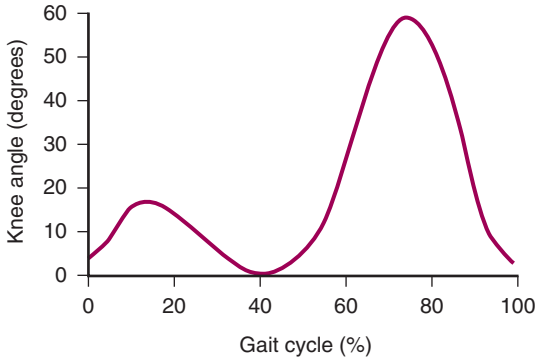

**Figure 6-3** Knee sagittal plane motion throughout the gait cycle. A positive value indicates knee flexion. For the first 60% of the gait cycle, the leg is in stance. The leg is in swing phase for the remainder of the gait cycle.

flexion of only five degrees). During midstance, the knee flexes to about 15 degrees, which occurs at 15% of the gait cycle. The knee joint is brought back into extension by midstance. At 50% of the gait cycle, opposite foot contact occurs. The weight is shifted to the opposite limb and the knee begins flexing. Toe-off occurs at 60% of the gait cycle. Peak knee flexion of 60 degrees occurs during the early portion of the swing phase. The knee motion can be described as two flexion waves, each starting in relative extension, progressing into flexion, and then returning again to extension. The first flexion wave, or stance phase knee flexion, acts as a shock absorber to aid weight acceptance. This curve peaks in early stance at opposite foot-off. The mechanical source for this shock absorber is the eccentrically contracting quadriceps muscles. The second flexion wave is necessary to clear the foot in the early swing phase. The knee is rapidly flexed beginning just after heel rise to a maximum in the swing phase just as the swinging foot passes the opposite limb.

The complexity of kinematic analysis increases substantially when one moves from planar analysis to 3-D analysis. The complexity of the analysis arises from a technical difficulty—that is, large rigid body rotations cannot be treated as vectors and hence do not obey the vectorial principles of transformation, independence, and interchangeability of operations. For finite spatial rotation, the sequence of rotations is extremely important and must be specified for a unique description of joint motion.[8,9] For the same amount of rotation, different final orientations will result from different sequences of rotation (Figure 6-4). However, with proper selection and definition of the axes of rotation between two bony segments, it is possible to make finite rotation sequence independent or communitive.[8,9] The concept of Eulerian angles has been adopted in the field of orthopedic biomechanics to unify the definition of finite spatial rotation. In the selection of reference axes, one axis is fixed to the stationary segment and another axis is fixed to the moving segment (Figure 6-5). In the knee joint, for example, the flexion/extension angle $\Phi$ occurs about a medial-laterally directed axis defined by a line connecting the medial and lateral femoral condyles. The axial rotation angle, $\Psi$, is measured about an axis defined by the line along the shaft of the tibia. The third axis, also defined as the floating axis, is orthogonal to the other two axes and defines abduction/adduction ($\Theta$). These rotations match the Eulerian angle description and are thought to be performed in such a way as to bring the moving segment from the reference orientation into the current orientation. The advantage of using this system for description of the spatial rotation of anatomic joints is that the angular rotations do not have to be referred back to the neutral position of the joint because the rotation sequence can be independent,

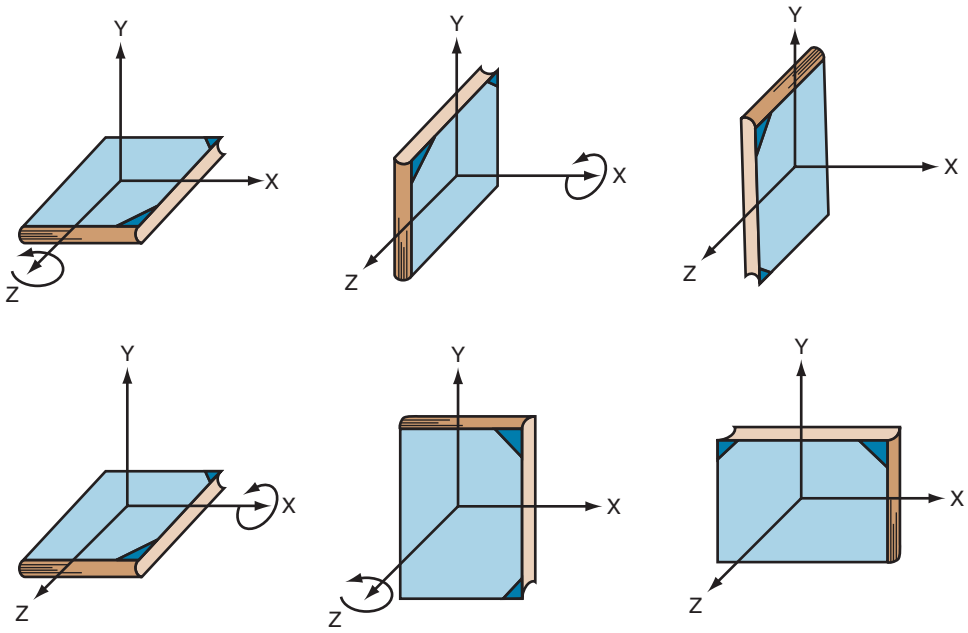

**Figure 6-4** Sequence dependence of rigid body motion. The object undergoes two rotations about the X-axis and Z-axis. The sequence of these rotations differs in the top and bottom rows. The result is that the final orientation of the object is different.

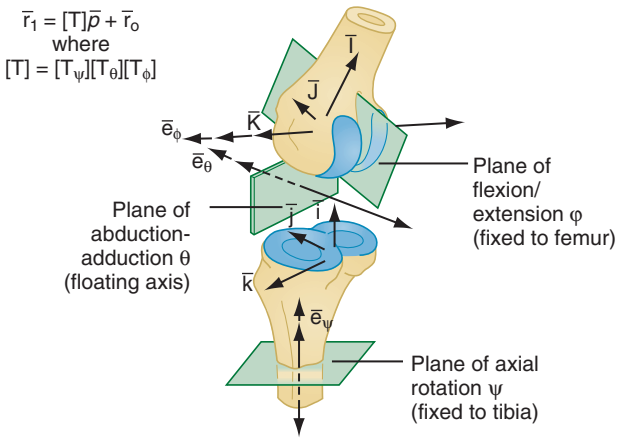

**Figure 6-5** Description of knee joint motion using the Eulerian angle system. An axis fixed to the distal femur defines flexion/extension motion, Φ. An axis, $e_\psi$, fixed to the proximal tibia along its anatomic axis defines internal external rotation, Ψ. A floating axis, $e_\theta$, which is orthogonal to the other two axes, is used to measure abduction-adduction, θ. The rotation matrix [T] between the proximal and distal joint segment is then given by the multiplication of the three rotation matrices associated with the rotations around the three axes (i.e., $[T] = [T_\psi][T_\theta][T_\Phi]$). *(From Chao EYS: Justification of triaxial goniometer for the measurement of joint rotation.* J Biomech *13:989–1006, 1980.)*

and thus the measurement can be easily obtained and related to anatomic structures.

A complete analysis of total joint movement (i.e., six degrees of freedom) can be obtained using markers embedded in the bone[10,11] or dual fluoroscopic imaging techniques.[12,13] This general unconstrained movement in 3-D space requires the description of three translations and three rotations to fully describe joint motion. The most commonly used analytic method for description of six-degrees-of-freedom displacement of a rigid body is the screw displacement axis or helical axis.[14-16]

## KINETICS

Kinetics is the study of the forces that cause motion of a rigid body. When unbalanced forces or moments are acting on a rigid body, it is under a nonequilibrium, or dynamic, condition, resulting in motion. Understanding the kinetics of human movement provides a fundamental understanding of the musculoskeletal system. Before one can begin to analyze the forces during human movement, some basic definitions are necessary and some basic assumptions must be made.

The key quantities in kinetics are *force*, *moment*, and *torque*. A force represents an interaction between two bodies. According to Newton's Second Law, force is any action that tends to change the state of rest or state of motion of a body to which it is applied. Forces can be contact forces (as when bodies touch each other) or field forces (as when bodies are separated by a distance, such as gravitational, electric, or magnetic forces). Forces are represented by *vectors*, which are composed of four components: magnitude, direction, sense, and position (also called *point of application*). The vector may be resolved into several component forces, usually along specified mutually perpendicular coordinate axes. Conversely, forces can be summed using vectorial addition.

A moment represents the turning, twisting, or rotational effect of a force. A moment is a vector. A moment is defined as the product of the force and the perpendicular distance between the line of action of the force and the axis of rotation of the motion that the force produces (Figure 6-6). Its magnitude is the force times the perpendicular distance to the axis of rotation. The direction of the moment is along the axis of rotation (or potential rotation) and thus perpendicular to the plane in which the twisting force is applied. The moment arm—that is, the distance used to calculate the moment—is the shortest distance from the force action line to the actual or potential pivot point of the system,

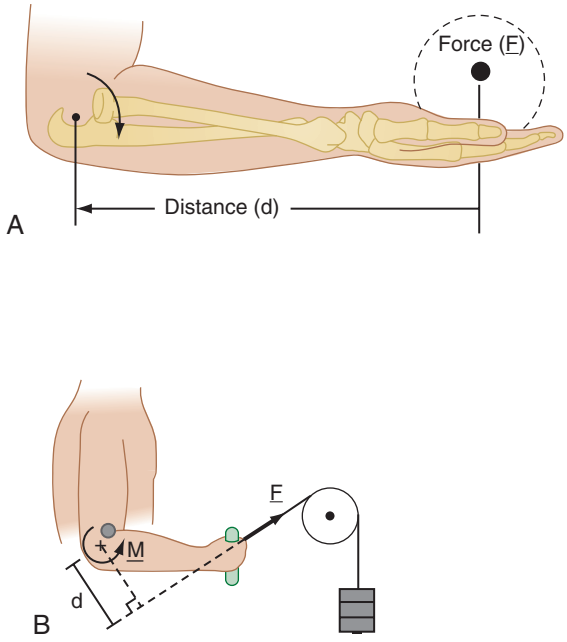

**Figure 6-6** The moment (M) of a force (F) about a point is equal to the force times the moment arm (d), which is the perpendicular distance between the point and the line of action of the force. The moment arm may **(A)** or may not **(B)** be the distance along the limb segment to the axis of rotation. The moment arm is always the shortest distance between the line of force application and the axis of rotation.

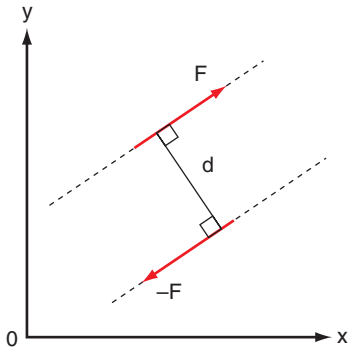

**Figure 6-7** A torque, or force couple, is created by two equal, noncollinear, and parallel but oppositely directed forces, F and –F. The magnitude of the torque is Fd, where *d* is the perpendicular distance between the two forces.

regardless of the state of motion. Skeletal motions are the result of moments applied by muscles that cross the joints on which they act. The moment of a force about an axis measures the tendency of the force to impart to the body a motion of rotation about a fixed axis.

A torque is a special type of moment that results when a pair of forces that have equal magnitude, parallel lines of action, and opposite senses act on a body (Figure 6-7). The magnitude of the torque is Fd, where *d* is the perpendicular distance between the two forces. The resultant force is zero because the two forces are equal and oppose each other.

Kinetics can be used to analyze forces affecting the musculoskeletal system. These forces can be classified as either external or internal. External forces represent the action of objects contacting the body, gravitational forces, or force due to inertia of the body. Internal forces are the body's responses to external forces. Internal forces consist of muscle, ligament, and joint contact forces. In general, the limb segments are assumed to be rigid, which simplifies the analysis because it is assumed that the structure does not deform under load. Further, joints are assumed to be frictionless hinges.

Statics is the study of forces acting on a body at rest. When performing a force analysis, the body or part of a body at equilibrium may be isolated from the environment, and the environment is replaced by forces acting on the system, resulting in what is called a *free-body diagram*. Because both forces and moments are vectors, they must sum to zero in each of the three perpendicular directions (reference system). Consider a person standing quietly (Figure 6-8). The person's weight (force of gravity) tends to pull the person toward the ground (Figure 6-8A). The person does not move downward because the ground is pushing up with a total force equal in magnitude to the individual's weight (Newton's Third Law). If the person has his or her weight distributed symmetrically, then his or her weight is evenly shared by each lower extremity (Figure 6-8A). The load under each foot can be represented by resultant ground reaction force (GRF) vectors, with one-half of the body weight supported by each foot. With one-half of body weight supported by each foot, the point of application of the resultant GRF passes approximately midway between the subject's two feet (Figure 6-8B). No motion occurs because the external forces (i.e., body weight and the GRF) are balanced—they are equal and opposite in magnitude. When the person leans to one side (Figure 6-8C), the GRF shifts in the direction that the person leans. Thus overall body posture can affect the GRF location. If the person leans more, he or she will become unstable (i.e., the downward body weight vector will fall outside the base of support). To remain in static equilibrium, the subject requires additional support (Figure 6-8D). The horizontal force applied to the upper body by the wall is balanced with an equal and opposite horizontal GRF component. Also, the two equal and opposite vertical forces are no longer aligned (i.e., collinear). They form a force couple that would tend to rotate the body in a counterclockwise direction. A second clockwise force couple formed by the two equal and opposite horizontal forces balances the counterclockwise force couple. As a result, the subject remains in both translational and rotational static equilibrium.

When unbalanced forces are present or no one is acting on a rigid body, it is under a nonequilibrium or dynamic condition, resulting in motion. Newton's Second Law of Motion links the kinematics of a body to its kinetics. The Second Law states, "If the resultant force acting on a body is not zero, the body will have an acceleration proportional to the magnitude of the resultant and in the direction of this resultant force." Analysis of the motion of the limb segments requires a set of governing equations and assumptions. The equations assume that each limb segment is a rigid body moving in 3-D space. Therefore, six scalar equations of motion define the general 3-D forces and motion of each limb segment:

$$\Sigma F = ma$$

$$\Sigma M = I\alpha$$

where ΣF is the sum of forces in each of three orthogonal directions, ΣM is the sum of moments, *I* is the moment of

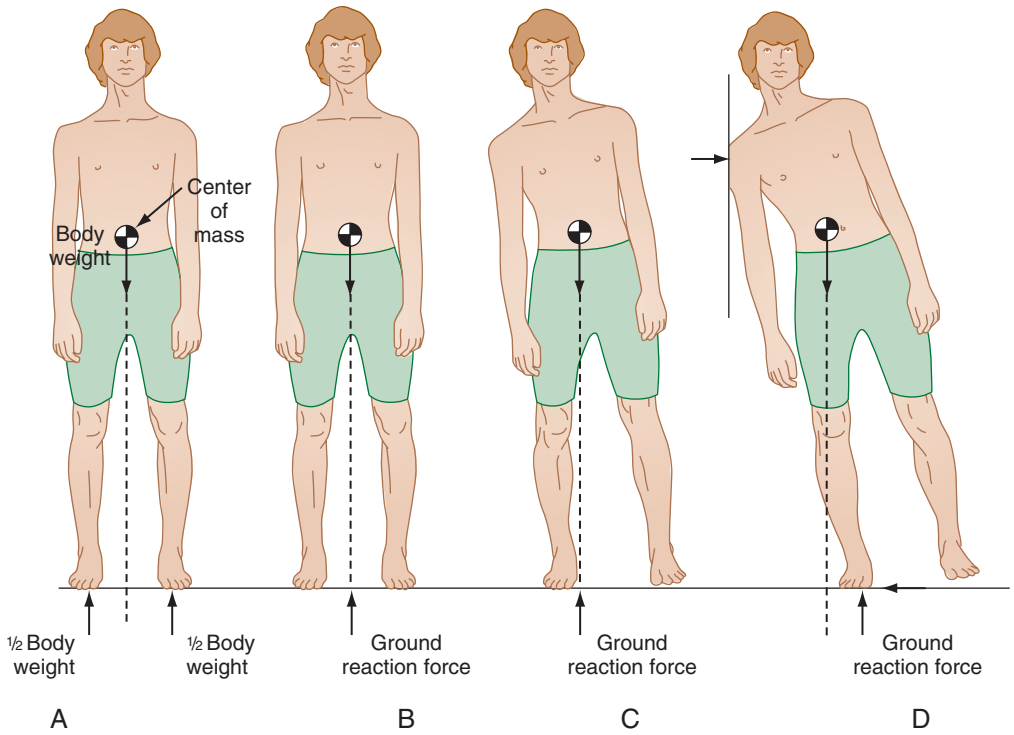

**Figure 6-8** Static force equilibrium. **A,** When a person stands quietly with the body weight evenly distributed on both feet, that person can be considered to be in static equilibrium. **B,** The loads under each foot can be combined into a single ground reaction force (GRF) equal to the sum of the forces under the two feet and located directly under the center of mass (COM), with a force equal to body weight. The GRF is located approximately midway between the two feet. **C,** As body weight is shifted laterally, the GRF also shifts in order to remain under the COM. **D,** When the body weight vector is shifted beyond the base of support (i.e., the lateral margin of the foot), an additional lateral force vector is required to maintain static equilibrium. *(From Davis RB, Kaufman KR: Kinetics of normal walking. In Rose J, Gamble JG, editors:* Human walking, *ed 3, Philadelphia, 2006, Lippincott Williams & Wilkins.)*

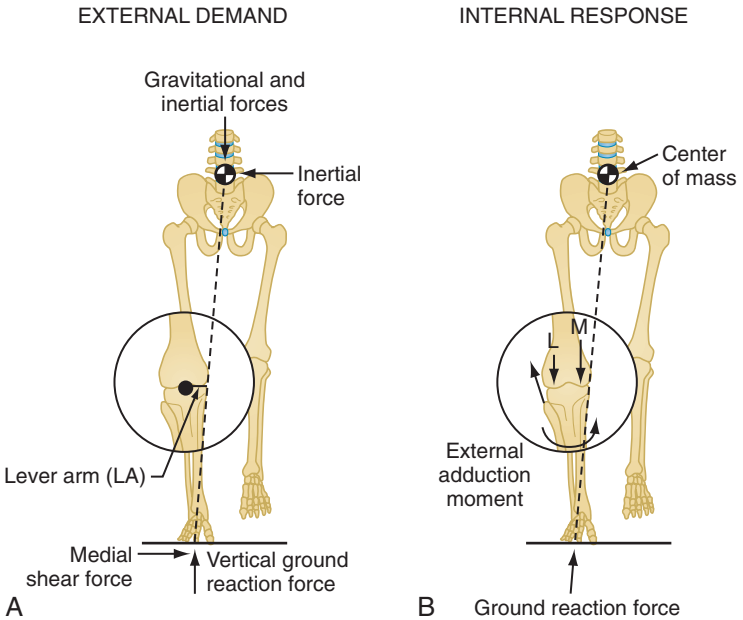

**Figure 6-9** Schematic of a person in single support during gait. **A,** External demand. The body weight and vertical ground reaction force (GRF) force couple tend to rotate the body clockwise. The medial shear GRF and the corresponding lateral inertial force produce a force couple that tends to rotate the body counter-clockwise. Thus the body is in dynamic equilibrium. **B,** Internal response. The resultant GRF passes medial to the knee joint, creating an external knee adduction moment. The external moment is balanced internally in the knee by creating a larger force on the medial tibial plateau (M) than on the lateral tibial plateau (L). Once again, the knee is in dynamic equilibrium.

inertia of the body, a is the linear acceleration of the body, $m$ is the mass of the body, and $\alpha$ is the angular acceleration of the body. Newton's Second Law makes it possible to calculate the forces acting on the musculoskeletal systems from measurements of segment motion and mass. During normal ambulation, there is a medial and vertical GRF that balances the body weight and lateral inertial force. The vertical GRF component generally passes lateral to the body's center of mass during gait (Figure 6-9A). The combined resultant GRF passes medial to the knee joint center, creating a load imbalance in the medial and lateral compartments of the knee. The medial and lateral

compartments of the knee carry more load than the lateral compartment of the knee (Figure 6-9B), and thus a higher degree of osteoarthritis (OA) typically develops in the medial compartment than in the lateral compartment. The resultant GRF vector creates a knee external adduction moment. Medial tibiofemoral OA is the most common form of OA, and it has become apparent that medial knee OA is at least partially mechanically driven. The peak external knee adduction moment has been implicated in the progression of radiographic OA[17] and has been identified as a marker of disease severity.[18,19]

## JOINT BIOMECHANICS

Diarthrodial joints connect long bones to allow force transmission and joint rotation. The type of joint articulating motion depends on the shape of the joint surfaces. For example, the hip is a congruent ball and socket joint, the elbow is a congruent hinge joint, the knee and proximal interphalangeal joint are bicondylar joints, and the carpometacarpal joint of the thumb is a saddle joint. In general, the joint articulating motion can be described in terms of sliding, spinning, and rolling (Figure 6-10). Sliding and spinning motions involve the relative translation of one surface against the other. Rolling has the least relative motion between articulating surfaces. The translational speeds range from 0.06 m/sec between the femoral head surface and acetabular surface during normal walking to 0.6 m/sec between the humeral head surface and glenoid surface during baseball pitching.[20]

Although diarthrodial joints experience an enormous amount of loading and motion, the cartilage surfaces undergo little wear and tear during normal conditions because of the special lubrication qualities of synovial fluid and the biphasic structure of the cartilage. Synovial fluid, which is secreted by the synovium into the joint space, contains mainly hyaluronate. Biomechanically, hyaluronate is a highly viscous liquid, with the shear stress depending on the rate of shear strain applied. As the shear rate increases, the viscosity of synovial fluid decreases. However, in the patient with rheumatoid arthritis, because of enzymatic degradation of the hyaluronate molecules, the viscosity of the rheumatoid synovial fluid does not have a normal shear rate dependency and is believed to be less effective in lubrication.[20]

Two lubrication mechanisms in the synovial joint provide minimal friction and cartilage wear: fluid film lubrication and boundary lubrication. During joint rotation, the sliding speed of the articulating surfaces and the viscosity of the synovial fluid create a thin film that is capable of supporting the load, resulting in fluid film lubrication. When the joint is loaded, the two articulating surfaces approach each other, and a squeeze film is generated to support the load. The pressure developed in the lubricating fluid carries the load

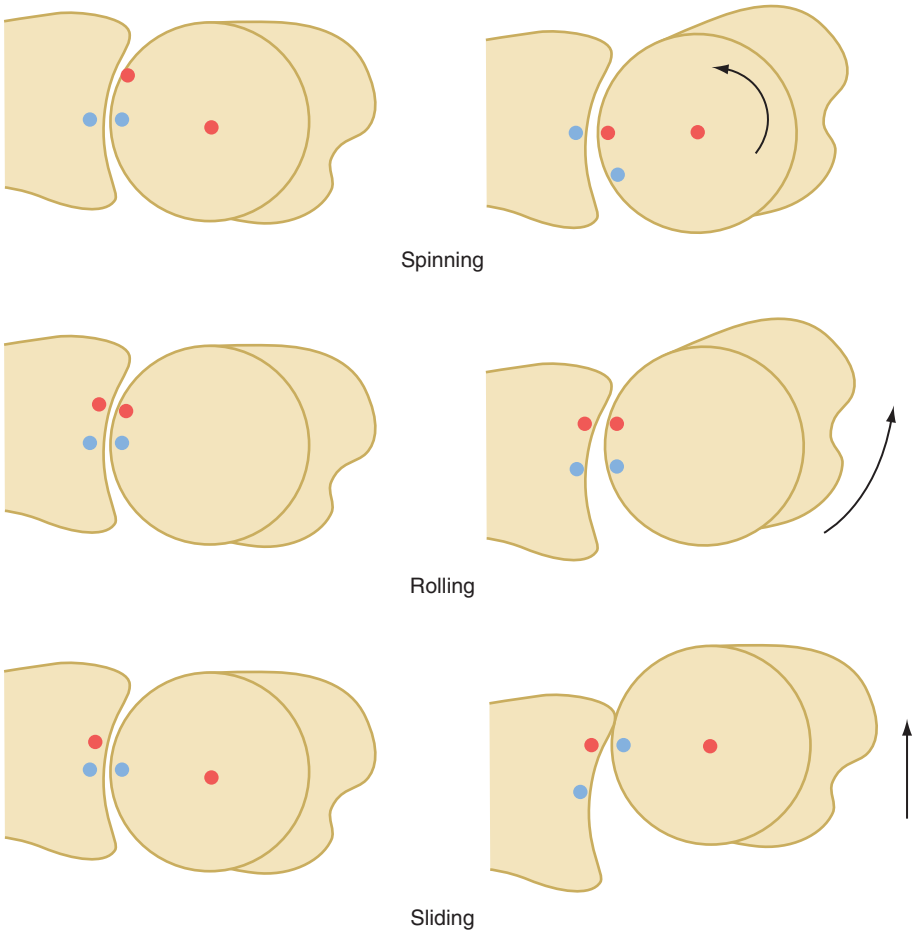

**Figure 6-10** The motions of joint articulation: spinning, rolling, and sliding. *(From Morrey BF, Itoi E, An KN: Biomechanics of the shoulder. In Rockwood CA, Matsen, F, editors:* The shoulder, *ed 2, vol 1, Philadelphia, 1998, WB Saunders, pp 233–276.)*

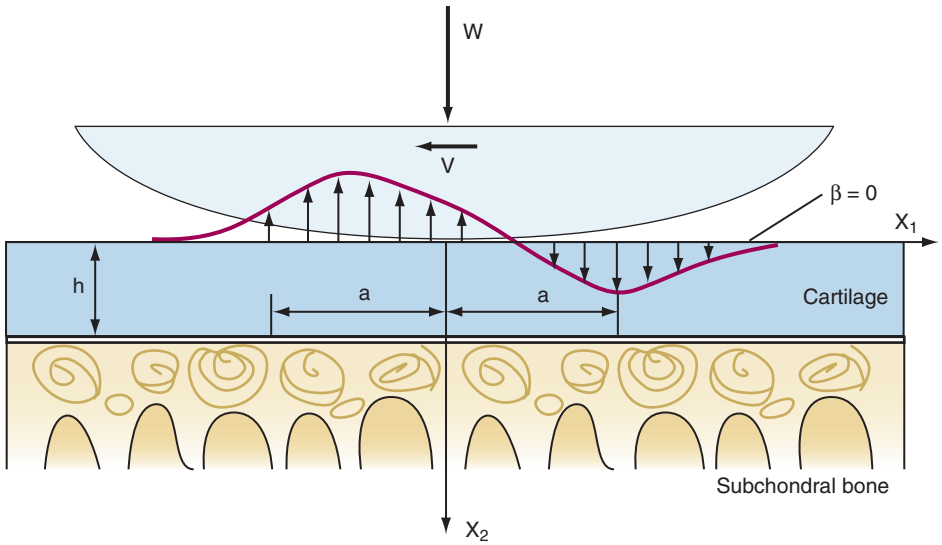

**Figure 6-11** Hydrodynamic lubrication. Surfaces moving relative to each other have an interposed viscous fluid that increases the pressure within the fluid to support the weight and keep the two surfaces separated. The pattern of predicted fluid exudation and imbibition over the articular surface (thickness = h) resulting from a frictionless, free-draining (β = 0) moving indenter is shown. V is the speed of the horizontal translation, and W is the resulting line load of a surface pressure distribution PA(×1) acting over a spread of |×1|<a. *(From Mow VC, Soslowsky LJ: Friction, lubrication, and wear of diarthrodial joints. In Mow VC, Hayes WC, editors:* Basic orthopaedic biomechanics, *New York, 1991, Raven Press, pp 245–292.)*

applied to the joint. The thin film of lubricant also produces a greater bearing surface. In addition, the cartilage is a biphasic porous medium. Water is bounded in the intrafibrillar space of the collagen matrix by proteoglycans. Intricate interaction of the mechanical stress, the electric charges, and the hydrodynamics result in a special fluid efflux pattern known as *elastohydrodynamic lubrication* (Figure 6-11). The fluid exudation ahead of and imbibition behind the moving contact point of the articulating surface further facilitates the lubricant film.[20]

On occasion, heavy loading exceeds the capacity that the lubricant film can support. In this situation, the cartilage surfaces are in direct contact, and lubrication is provided by the mechanism of boundary lubrication.[20] Boundary lubrication is accomplished by a monolayer of glycoprotein called *lubricin*, a superficial zone protein. In the pathologic condition of OA, the structural properties of cartilage such as porosity and permeability are altered. The fluid efflux and the synovial fluid film are diminished, and boundary lubrication is the remaining mechanism of joint lubrication.

## JOINT CONSTRAINT AND STABILITY

The human body is able to perform complex motions because the joints allow multiple degrees of freedom between articulating bones. Because of the variations in anatomic structures of the joints, various limbs have different movement characteristics and load transmissions. Adequate joint stability that balances motion and loads is necessary for a joint to function properly. Chronic disease or traumatic injury may cause damage to joint tissue, thus compromising the constraints and stability of the joint. To improve the diagnosis and treatment of such joint disorders, it is essential to understand the basic mechanics of the constraint, which provides stability. The anatomic structure responsible for joint constraint can be divided into passive and active elements. Passive elements, consisting of the capsulo-ligamentous structures and bony articulating surfaces, provide static constraints of the joint. The active elements include muscle-tendon units, which provide dynamic constraints of the joint.

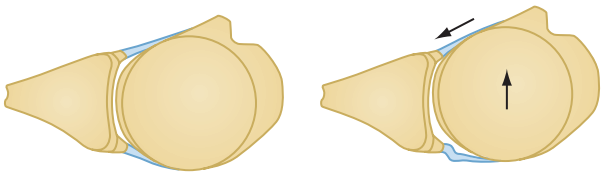

**Figure 6-12** When the joint is loaded or displaced, the capsulo-ligamentous tissues are stretched and the passive tensions develop. The amount of tension developed depends on the amount of deformation, as well as the material properties of the soft tissue. The location of the capsulo-ligamentous attachment on the bone and the direction of bony movement regulate not only the amount of deformation but also the direction of passive tension in stabilizing the joint.

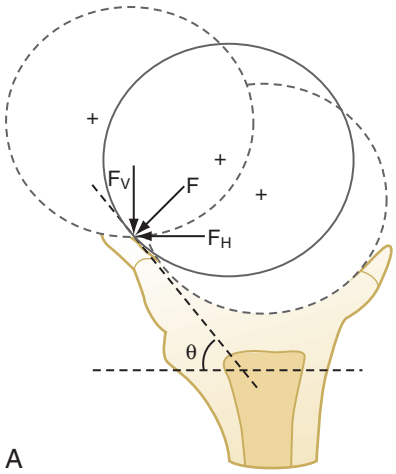

The contribution of capsulo-ligamentous structures to joint stability and constraint are determined by the change in length, the line of action, and the tissue material properties (Figure 6-12). For a given loading and displacement of the joint, the greater the elongation of the soft tissue, the higher the passive tension generated by that tissue. However, the specific contribution of such passive tension to joint constraint further depends in turn on the relative line of action of the capsulo-ligament structures. Therefore, the relative locations of the origins and insertions of the ligaments may determine the contribution of the ligamentous tension in resisting joint displacement in three orthogonal directions. Surgical alternations of the soft tissue attachment to the bone would therefore change the joint constraints.

Lengthening and shortening of the capsulo-ligament structures during joint loading and movement determine the tissue deformation. The tissue material properties, along with the amount of deformation, will determine the structure passive tension. For the same amount of deformation,

the stiffer the tissue, the higher the tension will be, and the softer the tissue, the lower the tension. Alterations of the material properties due to physiologic and pathologic conditions definitely alter the joint constraint and the articulation. For example, the tight posterior capsule of a baseball pitcher limits the range of physiologic motion. On the other hand, the softening of capsulo-ligamentous structures during pregnancy and in persons with rheumatologic diseases could potentially lead to abnormal motion and contact stress on the joint surface. These alterations of soft tissue material properties must be considered as potentially critical factors in initiating early joint cartilage degeneration and may lead to the vicious cycle that perpetuates arthritis.

Experimentally, the significance of various passive anatomic structures to joint stability has been assessed using two methods: the stiffness test and the laxity test. The stiffness test is commonly used to determine the relative contributions of individual anatomic elements to joint constraint. The laxity test demonstrates the outcome of joint instability when one or more constraining units are compromised. In the stiffness test, the joint is displaced under controlled testing and the corresponding load is monitored. Based on the joint load–displacement curves, it is obvious that the load required to displace the joint is higher when all the ligaments are intact than when a ligament is lacerated. The difference in the constraining load between these two curves at the same joint displacement represents the contribution of that particular sectioned ligament to the joint constraint. Because the capsulo-ligamentous structures are passive tissues, as long as the joint displacement is controlled and experimentally reproduced, the relative contributions of individual tissues will not be dependent on the sectioning sequence of soft tissue. Contrary to the stiffness test, during which displacement is varied and load is measured, in the laxity test, a specific load is applied to the joint and the extent of joint displacement is measured. Joint laxity is documented with changes in displacement as anatomic elements are removed. The joint laxity as observed and measured provides more of a clinical scenario of the joint instability experienced by a patient who has sustained a similar soft tissue injury.

In addition to soft tissue constraints, the joint articulating surface is an element that provides joint constraint and stability. Theoretically, its significance to joint stability is determined by both the geometric shapes of the joint surfaces and the amount of compressive force encountered between those two surfaces (Figure 6-13A). When two curved surfaces articulate, a vertically applied force will induce either a transverse displacement or a transverse constraining force. The greater the congruency between the curved articulating surfaces, the greater the induced horizontal joint constraint force. This mechanism is sometimes referred to as *concavity-compression*. In the shoulder joint, for example, the relative translations between the glenoid and humeral head and the forces resisting translation were recorded. The stability ratio, defined as the peak translational force divided by the applied compressive force, was higher in the hanging-arm position than in glenohumeral abduction (Figure 6-13B). The highest stability ratio was detected in the inferior and superior directions, and the anterior direction was associated with the lowest stability ratio. Resection of the glenoid labrum resulted in an average

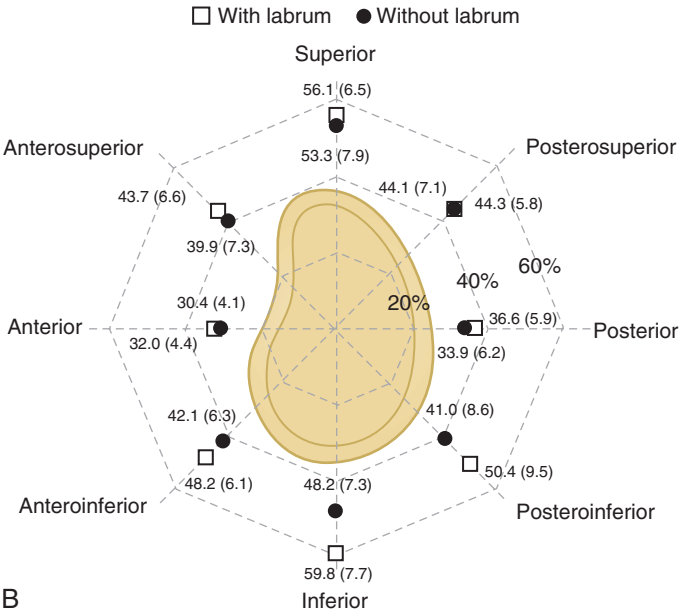

**Figure 6-13** Contributions of the articulating surface to joint stability. **A,** Transverse displacement of bone in the curved joint requires elevation against the articulating surfaces. With compressive $F_V$ applied, any transverse movement will encounter a resistance ($F_H$). If either the mating joint surface is flat (i.e., $\theta = 0$) or a compressive force, $F_V$ is not available, there will be no transverse constraint ($F_H = 0$). **B,** The stability ratio, defined as transverse constraint force $F_H$ divided by the applied compressive force $F_V$, was measured in the glenohumeral joint with the labrum intact or absent. This measure indicates the stability through the joint-surface interaction, independent of the magnitude of the compressive force applied.

decrease in the stability ratio of 10%. In the treatment of traumatic recurrent anterior shoulder instability, patients with a large osseous glenoid defect are at risk for recurrent instability after arthroscopic Bankart repair. Bone grafting performed in shoulders with a large osseous glenoid defect to restore the articulating surface provides excellent clinical outcomes.

To benefit from the concavity-compression joint constraint, a compressive or oppositional force across the joint surface is required. This joint compressive force is usually generated by muscle contraction. The relative location and direction of the resultant joint force to the available articulating surfaces will determine the potential stability of the

joint. For example, in the glenohumeral joint, if the resultant force is well located at the center of the glenoid articulating surface, the joint is considered stable. When the resultant force is directed outside the available joint surfaces, joint dislocation is most likely. However, when the resultant force is located within the joint surfaces but more toward the rim of the glenoid surface, the potential exists for joint subluxation. The interaction of muscle force resulting in a resultant joint constraint force is illustrated later.

Intra-articular or intracapsular pressure is the other component of passive and static joint constraint (Figure 6-14). The joint is usually surrounded by a capsule and sealed with synovial tissue. When the capsule is intact, any distraction force stretches and deforms the capsulo-ligamentous structure and will generate negative intra-articular pressure. This negative intra-articular pressure will counteract further displacement. When the joint capsule is vented, such negative pressure can no longer develop and cannot constrain the joint. Negative intracapsular pressure is therefore a constraint of all joints. However, it is especially important for joints under gravitational distraction, such as the shoulder joint.

Active muscle contraction is also important for joint stability. Proper coordination of muscle contraction provides dynamic joint constraint. On the other hand, deficiency of muscle innervation or a tendon defect can result in unfavorable joint constraint and lead to joint instability. Importantly, muscle force can act as either a joint stabilizer or a joint dislocator. The contribution of muscles to joint constraint is similar to that of passive capsulo-ligamentous tension. It is determined by the line of action of the passive and active tension of the muscle. Based on the relative position of the bony structure and the direction of the joint displacement, the same muscle-tendon structure can contribute differently to joint constraint. When the joint is spanned by multiple muscles, the coordination of muscle contraction will ultimately determine the dynamic joint stability. For example, the contributions of muscle contractions to the articulating surfaces of the shoulder can be described in terms of the normal and shear directions (Figure 6-15). The shear component has direct influence on the transverse translation of the bony element at the joint. In contrast, the normal force component of the muscle provides the compressive force to bring the surfaces together. A glenohumeral joint with a lax capsule and loose ligaments might be dynamically stabilized if the glenoid concavity is maintained and the function of the external and internal rotators, which are efficient stabilizers, is enhanced. On the other hand, in a patient with a rotator cuff tear, the pull of the major movers such as deltoids during arm elevation or

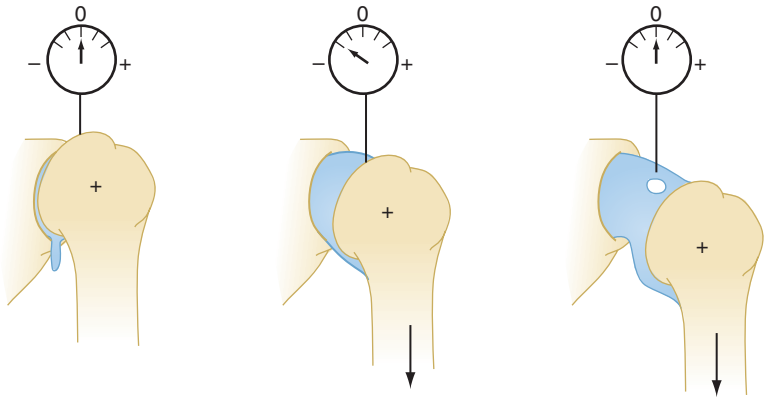

**Figure 6-14** Effect of negative intra-articular pressure on shoulder joint stability. In the normal situation, traction on the arm causes an increase in negative intraarticular pressure, and joint distraction is constrained. On the contrary, if the capsule is vented and air or fluid is introduced into the joint, traction on the arm no longer affects the intraarticular pressure; instead, the joint will be subluxed inferiorly.

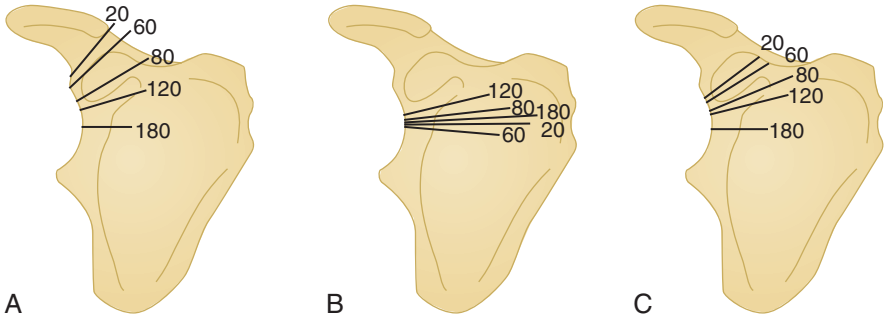

**Figure 6-15** Coordination of the muscle contractions to accomplish a given task is demonstrated by the situation when the deltoid and rotator cuff muscles work together to elevate the shoulder joint. **A,** For patients with a rotator cuff tear, the shoulder elevation is accomplished by the deltoid muscle alone. The resultant joint force is directed superiorly because of the line of action of the deltoid muscle. In this situation the joint is not stable and superior subluxation and migration results. **B,** On the other hand, when elevating the shoulder with the rotator cuff muscle alone, the resultant joint force points toward the center of the glenoid surface, which makes the joint very stable. However, the magnitude of the joint resultant forces are relatively high, which may not be ideal for the cartilage tissue. **C,** Ideally, shoulder elevation is accomplished with a combination of the deltoid muscles as the prime mover to provide strength and power, along with the rotator cuff muscles as the sterling in directing the joint resultant force to keep the joint in a more stable condition.

forward rotation will result in a resultant joint force in the superior and anterior directions, with resulting superior impingement or anterior instability.

In general, muscle contraction will generate moments about all three axes of rotation of a given joint. However, when the constraints from other periarticular soft tissues are not available, the muscle will be primarily responsible for maintaining stability during the joint's rotation. If a muscle crosses multiple joints, the effect of muscle recruitment depends on the moment arms of all the joints it spans. The concept of biarticular muscle is of extreme clinical importance. For example, when considering rehabilitation after reconstructive surgery of the anterior cruciate ligament, the goal is to strengthen the muscles without excessive tension being placed on the ligament. Quadriceps loading, especially with the knee in a near extended position, would result in an anterior joint shear force and anterior displacement of the tibia with respect to the femur. This shear force would induce tension in the anterior cruciate ligament. The concept of kinetic-chain exercise has been used extensively to address this problem. During closed-kinetic-chain–type exercises such as the squat and the leg press, the foot is fixed and knee motion is accompanied by motion at the hip and ankle joints. The ground reaction force causes external flexion moments at both the knee and hip joints. The antagonistic muscle action of hamstrings at the knee joint is recruited to balance the hip flexion moment. Co-contraction of quadriceps and hamstrings at the knee joint reduces the anterior joint shear force and the tension in the anterior cruciate ligament.[21]

## MECHANICAL LOADING ON TENDON

Tendons transmit the muscle contraction force to bone in order to cause limb movement. The force transmitted is primarily tensile force. In addition, specific portions of tendons also experience compression and shear force. Compression occurs when the tendon path is altered around a bony structure or pulley system. As a tendon is subjected to local compression, the mechanical loading does not distribute evenly within the tendon. The pressure decreases in deeper layers while the tension increases to the outer part. The overlapping of pressure and tension in the transition zone results in shear force inside the tendon. Furthermore, during tendon gliding against the surrounding tissues, shear force is generated on the contact surfaces of the tendon and surrounding tissues.

A tendon gliding through a pulley is analogous to a belt wrapped around a fixed mechanical pulley (Figure 6-16). As the tendon moves proximally, the tensions in the tendon proximal and distal to the pulley ($F_p$ and $F_d$) are related to the angle ($\theta$) of the tendon segments wrapped around the pulley or arc of contact and the friction coefficient ($\mu$).[22] Thus,

$$\text{Friction} = F_p - F_d = F_d(e^{\mu\theta} - 1)$$

This simple relationship clearly demonstrates the importance of the angle of contact and the friction coefficient. It explains why avoiding awkward joint postures is important ergonomically to reduce repetitive injury of soft tissue.

The three modes on mechanical loading (namely, tension, compression, and gliding) can be demonstrated by

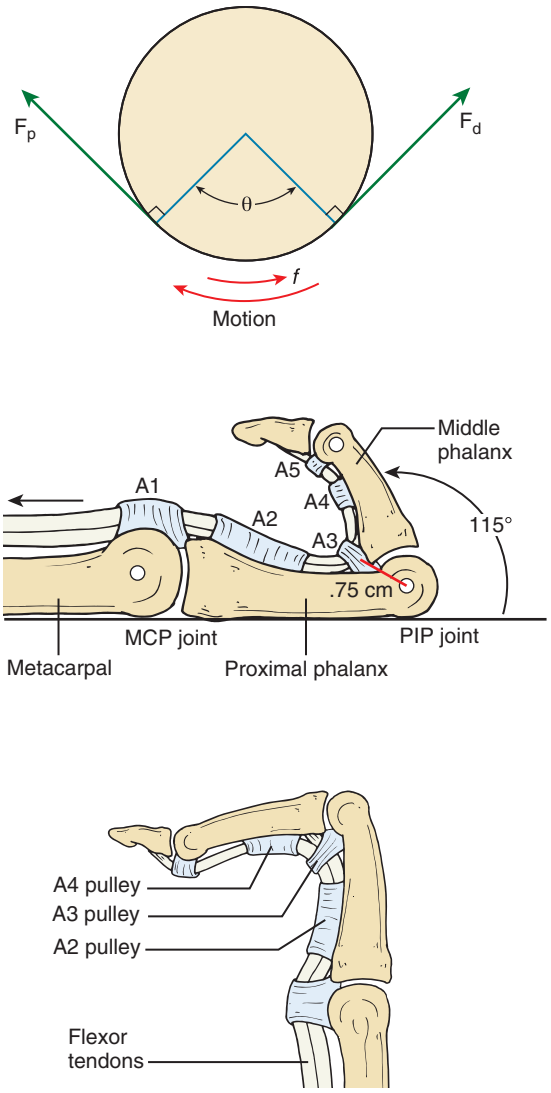

**Figure 6-16** To move the finger, the tendon glides through a pulley, which is analogous to a belt wrapped around a mechanical pulley. The tendon force must overcome the gliding resistance of the tendon and generate sufficient force to move the external load. The friction, *f*, of a tendon against the surrounding tissue is in the opposite direction of the tendon motion. The sliding resistance (friction) is the difference between the tension on the distal and proximal ends across the pulley ($F_d$ and $F_p$ respectively). MCP, Metacarpophalangeal; PIP, proximal interphalangeal.

three scenarios at the shoulder joint (Figure 6-17). The short head of the biceps brachii tendon is an example of the first scenario, in which the tendon mainly experiences tensile force alone. The second scenario, in which the tendon encounters tensile force and compression together, occurs internally at the bone insertion site of the supraspinatus tendon. The insertional area of the tendon encounters tensile force, as well as compression resulting from the transverse contact of the tendon with the attached bone. The third scenario occurs when the tendon is simultaneously subjected to tension, compression, and gliding. The long head of the biceps brachii tendon, where it passes through the bicipital groove, demonstrates an example of the third scenario. The supraspinatus tendon also fits the scenario, as well as the second scenario. Subacromial impingement of the supraspinatus tendon generates high

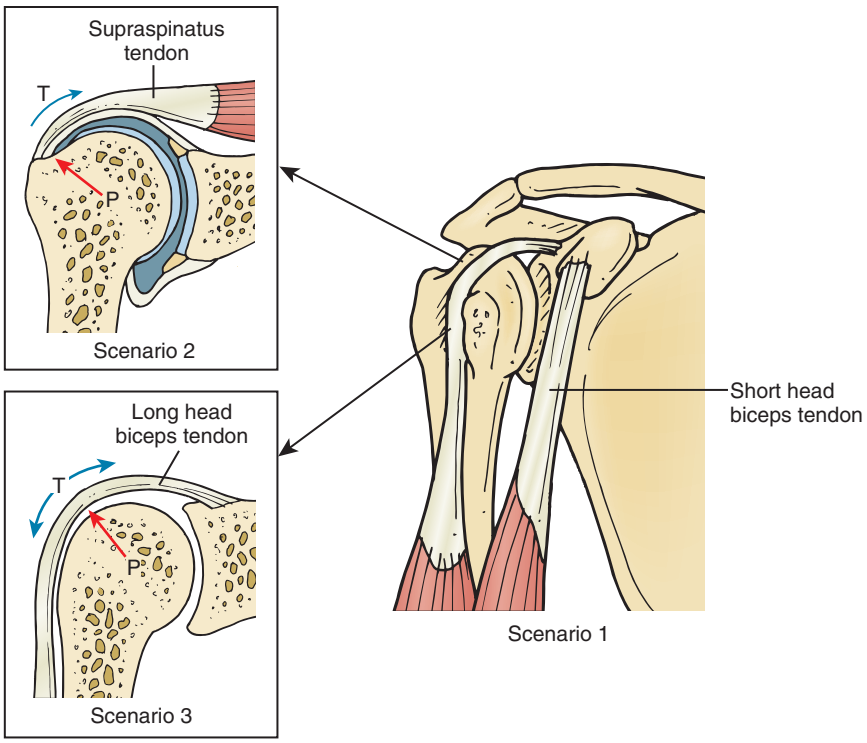

**Figure 6-17** Supraspinatus tendon and long head and short head biceps tendons. Scenario 1: tensile force only. Scenario 2: tensile force and compression. Scenario 3: tensile force and compression with gliding.

compressive stress that varies along the supraspinatus tendon, depending on humeroscapular elevation. The mode of mechanical tendon loading is potentially correlated to the incidence of tendon degeneration. The tendons in the first scenario rarely experience degenerative tendinopathy. Tendons commonly affected with tendinopathy are represented in the other two scenarios, in which the affected areas normally sustain compression and shear force with or without gliding in addition to tensile force.

In summary, knowledge of biomechanical principles can help explain many commonly encountered situations in the musculoskeletal system that contribute to musculoskeletal disease.

CHAPTER 7

# Regenerative Medicine and Tissue Engineering

Frank P. Luyten • Cosimo De Bari • Francesco Dell'Accio

**KEY POINTS**

- **Because tissue repair mimics the cellular and molecular cascade of embryonic tissue formation, investigating the role of developmental pathways in joint and skeletal disorders/diseases could identify novel therapeutic targets.**
- **Tissue repair and regeneration are partially determined by genetic factors.**
- **Tissue engineering has adopted the concept of biomimetics of in vivo tissue development. *Developmental engineering* is the term used to describe novel methodology for the rational and accurate design of robust, well-controlled manufacturing processes of "biological spare parts."**
- **Cellular therapeutics and their combination products are complex with regard to their mechanism of action and manufacturing and have evolved into advanced therapy medicinal products with a specific regulatory path.**
- **Recent advances in regenerative medicine and tissue engineering relevant to rheumatology have entered clinical practice and include the biologic repair of joint surface defects and bone healing.**

Destruction of joint tissues is ultimately the disabling outcome of most forms of inflammatory or degenerative arthritides. The need for repair and regeneration of joints and joint-associated tissues is becoming more relevant as the dramatic advances of targeted treatments and improved disease management have allowed much more efficient control of inflammation and joint destruction.

In view of this situation, other aspects of joint biology deserve more attention—notably, and most importantly, the mechanisms driving tissue response and repair.[1] Indeed, to restore the balance between tissue destruction and tissue repair (Figure 7-1), we should be looking at the more complete picture, that is, the "systems biology" of the joint as the organ of the rheumatologist. Introducing regenerative medicine provides a significant opportunity to restore joint homeostasis and thus possibly provide a cure. Targeting repair has entered our discipline, and investigating the potential to activate and enhance joint tissue repair mechanisms has become a prime goal.

Regenerative medicine and tissue engineering (TE) seek to repair or regenerate damaged tissues and organs, regardless of the cause of the damage, without leaving scar tissue, thereby restoring both the structure and function of the damaged tissues/organs. Nature demonstrates that this goal is achievable, because successful wound healing and fracture repair are processes that happen routinely after birth. We also know, as demonstrated in fetal surgery, that scarless repair is partially dependent on age and context. Thus it is attractive to envision that, with an in-depth understanding of the repair processes at the cellular and molecular level, we may be able to intervene quickly at the time of injury and guide the healing process more appropriately, thereby preventing scar formation.

Postnatal tissue healing mimics developmental processes of tissue formation. For example, it appears that the process of rebuilding an adult limb, such as seen in the axolotl, but also during fracture healing in higher species, has many similarities with how the limb forms in the first place in the embryo, and particularly requires signaling mechanisms to specify the final pattern. Thus both limb formation and limb regeneration are likely to use the same molecular pathways.[2] The remarkable advances in developmental biology during the past several decades have now provided the knowledge platform to advance into novel regenerative approaches in postnatal life. These advances not only include our understanding of the mechanisms of body axis formation and organogenesis but also impressive progress in stem cell biology, including the regulation of stemness, stem cell niches, lineage specification and cell differentiation, and the critical molecular pathways involved. We are now in a position to enter a new era in regenerative medicine and TE.[3,4] In this chapter we will review the approaches that seek to repair damaged and diseased tissues and, in particular, synovial joints and skeletal structures.

When we seek to repair tissues, two mechanistic approaches are possible. The first approach consists of enhancing intrinsic repair mechanisms with stimulation of cell proliferation, differentiation and tissue metabolic activity, and recruitment of endogenous progenitor populations into the damaged tissue. The second approach becomes necessary when intrinsic repair is not feasible or insufficient and entails extrinsic repair, that is, TE approaches via manufacturing of cellular and/or combination products that can contribute mostly locally to tissue repair (Figure 7-2).

## INTRINSIC REPAIR MECHANISMS

### Genetic Basis of Tissue Repair

For many years it has been commonly accepted that "cartilage…when destroyed, it is never recovered."[5] This statement probably still holds true for established defects

(e.g., defects that have failed to heal and have become chronically symptomatic, and therefore come to the attention of the clinician); however, prospective imaging and arthroscopy studies have revealed that even in adult humans, acute cartilage defects are much more prevalent than suspected, even in asymptomatic subjects, and have some capacity for spontaneous healing (reviewed in reference 6).[6] Such studies showed that roughly half of adults without joint symptoms have chondral defects[7,8] and that about a third of such lesions improve spontaneously, a third remain stable, and the remainder worsen.[7,8] The outcome appears to depend on a number of risk factors including age, co-existing osteoarthritis (OA), high body mass, female sex, abnormal bone geometry, and the presence of bone marrow lesions.[9,10]

A prospective, magnetic resonance imaging (MRI)-based study in a sib-paired cohort[11] identified a very high (>80%) heritability of the rate of progression of chondral defects. Nonetheless, in contrast with the remarkable progress in the identification of genetic markers predisposing to OA,[12,13] no quantitative trait linkage and association analysis study is available yet in humans with regard to the capacity of repairing cartilage defects.

Although the evidence for the heritability of cartilage repair capacity in humans is still circumstantial, findings of animal studies are more convincing. Comparing the capacity of different inbred mouse strains to heal full-thickness cartilage defects, Eltawil et al.[14] demonstrated that different inbred mouse strains have a dramatically different capacity to heal cartilage defects and to avoid the onset of post-traumatic OA. This finding supports the concept that the repair capacity has a genetic component. The development of such an animal model lends itself to genetic analysis. For instance, Rai et al.[14a] took advantage of the different healing capacity of two strains of mice: LG/J, which can efficiently heal joint surface defects and experimental wounds to the cartilage of the pinna of the ear, and SM/J, which are poor healers. A set of recombinant inbred lines were obtained by crossing the two strains. Thus it was found that both the capacity of healing joint surface defects and the capacity to heal ear wounds were highly heritable and that they correlated with each other. This finding suggests that the capacity to heal cartilage is inheritable by itself, whether the cartilage is on the surface of a diarthrodial joints or in the pinna of the ear, and is not just dependent on the resistance to develop OA or on factors extrinsic to cartilage such as bone shape/quality or synovitis. The fact

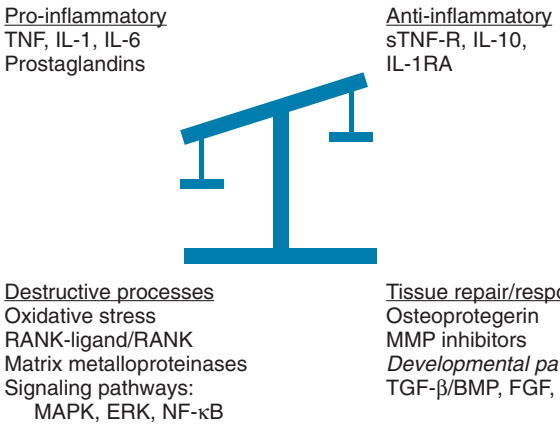

**Figure 7-1** The "systems biology" view of chronic arthritis. The severity and outcome of disease is determined by the balance between inflammation/destructive processes and anti-inflammatory signals with repair attempts. **Figure 7-2** In traditional tissue engineering *(top)*, the repair tissue is generated and matures in the laboratory and is inserted in the defect directly. No maturation is expected to happen in vivo. In cell-based approaches *(middle)*, nondifferentiated or partially differentiated in vitro expanded cells are implanted. Differentiation and remodeling is expected to happen in vivo. In cell-free approaches *(bottom)*, only biomaterials and bioactive molecules are implanted, which, in vivo, attract resident progenitor cells and induce their patterning and differentiation.

that homeostatic mechanisms affect the rate of OA progression suggests that the same genes associated with the predisposition to OA might affect also the capacity to repair; however, this assumption has never been rigorously tested experimentally. It must be remembered that other independent aspects come into play in the determination of OA progression, including joint shape,[17,18] body mass index, inflammation, and several other aspects that are also under genetic control.[19] Therefore allelic variants that affect such parameters will also affect OA predisposition, independently from repair mechanisms intrinsic to the joint. Nevertheless, it is interesting that signaling molecules belonging to the same pathways have been associated with both OA and regeneration. For instance, loss of function alleles of the WNT inhibitor FRZB are associated with OA predisposition,[20-22] and a single nucleotide polymorphism of the WNT ligand WNT-3A has been associated with the heritability of cartilage repair capacity in mice.[23]

## Signaling Pathways

Because postnatal tissue repair mimics tissue formation during development in many aspects, it is likely that developmental pathways involved in the formation of the joint and joint-associated tissues could be potential targets to enhance postnatal tissue repair.

Typical developmental pathways critically involved in the formation of skeletal tissues and structures such as the synovial joints are the transforming growth factor (TGF)-β superfamily, including the bone morphogenetic proteins (BMPs) and growth differentiation factors (GDFs), the Wnt family of proteins, the fibroblast growth factors (FGFs), the hedgehog proteins, parathyroid hormone (PTH)/PTH-related protein (PTHrP), and Notch signaling. In this chapter we select a few examples of how these signaling pathways are involved in joint formation and their role in postnatal joint repair, with a specific focus on some of these pathways that have led to advances in early clinical development in arthritic diseases.

### Transforming Growth Factor-β/Bone Morphogenetic Protein Signaling

Recent data have highlighted the relevance and critical role of the members of the TGF-β superfamily (TGF-β, BMPs, and GDFs) in the biology of articular cartilage, bone, joints and joint-associated tissues, both during development and in postnatal tissue homeostasis, repair, and tissue response to injury and ageing. TGF-β has been shown to be involved in the maintenance and ageing of articular cartilage and OA.[24] BMPs have been reported to play major roles in articular cartilage metabolism, with BMP-7/osteogenic protein-1 (OP-1) being of particular interest.[25,26] In addition, the data indicate that modulation of TGF-β/BMP downstream receptor-Smad signaling plays an essential role in both the regulation of chondrocyte differentiation and the development and progression of OA.[27] Therefore, given the overwhelming evidence of the regenerative potential of this family of growth and differentiation factors in preclinical models, it is not surprising that their therapeutic use is being explored in clinical studies and in indications such as long bone healing and OA. In addition, intense research is ongoing to identify modulators of the TGF-β/BMP receptor/Smad signaling pathways through peptide technology (peptidomimetics) or small molecule screens.[28] Because the synovial joints allow for local treatments, it is expected that some of the newly identified compounds will first be tested in local applications, such as joint surface repair and monoarticular OA. BMP devices are already in the clinic for orthopedic applications such as spine fusion and the healing of nonunions.[29,30]

### Fibroblast Growth Factor Signaling

Extensive investigations have identified FGFR3 signaling as a key regulator of chondrocyte and osteoblast function, both during development and postnatally. In particular, absence of signaling through FGFR3 in the joints of *Fgfr3*$^{-/-}$ mice leads to premature cartilage degeneration and early signs of OA.[31] One of the key ligands of FGFR3 signaling appears to be FGF18.[32] In the postnatal joint, FGF18 has significant anabolic effects on cartilage metabolism. Intra-articular injection of FGF18 induced a dose-dependent increase in cartilage formation and a reduction in cartilage degeneration scores in the medial tibial plateau of rats with OA.[33] Importantly, this effect was seen only in joints affected by OA, not in normal rat joints, suggesting a specific response to tissue injury. At the molecular level, this joint-protective effect may be due partially to its interaction with other signaling pathways such as BMP signaling by repressing noggin, a BMP antagonist.[34] These findings, combined with the increased understanding of FGF18 signaling in postnatal cartilage and bone biology, led to the development of a local treatment with FGF18 (sprifermin) and the design of clinical trials (clinicaltrials.gov) in both patients with cartilage lesions and patients with OA of the knee.

### Wnt Signaling

Overwhelming evidence indicates a critical role for Wnt signaling in cartilage and bone biology, with a specific relevance to osteoporosis and OA (for a review, see Luyten et al.[35]). Although Wnt signaling is essential for the development and homeostasis of synovial joints,[36-40] genetic studies in humans[20] and experimental data[22,41,42] demonstrate that excessive/uncontrolled activation of Wnt/β catenin signaling leads to reprogramming of articular chondrocytes toward catabolism or loss of their stable phenotype with subsequent loss of articular cartilage tissue structure and function. In particular, loss of function allelic variants of the Wnt inhibitor FRZB were associated with increased predisposition to develop OA.[20] Similarly, disruption of the *Frzb* gene in mice resulted in increased activity of the WNT signaling pathway and consequent increased bone stiffness and enhanced cartilage damage.[22] Importantly, upon induction of experimental OA, *Frzb*$^{-/-}$ mice showed greater cartilage loss than their wild-type counterparts.[43] Increased cartilage damage in *Frzb*$^{-/-}$ mice was associated with higher levels of β-catenin dependent Wnt signaling and with higher expression levels of matrix metalloproteinase (MMP)-3. It was also demonstrated that FRZB can directly inhibit MMP-3, probably through the netrin domain, indicating the potential complexity of the underlying mechanisms of observed phenomena.[44]

Tightly regulated Wnt signaling is critical for the homeostasis of synovial joints.[38,40,45,46] Diarra et al.[47] demonstrated that in human and experimental murine arthritis, the inflammatory cytokine tumor necrosis factor drives the excessive production of the Wnt antagonist DKK1. The consequent excessive inhibition of the Wnt pathway was found to be responsible for bone resorption (erosions), typical of this arthritis model, as well as of rheumatoid arthritis (RA). Accordingly, blocking DKK1, and therefore de-repressing Wnt signaling, resulted in reversal of bone damage.[47] In the same model, direct activation of WNT signaling using the Wnt agonist R-Spondin 1 reversed not only the bone damage (also achieved with DKK1 blockade), but also the cartilage damage.[48] Therefore, both uncontrolled suppression and activation of the WNT signaling may lead to catabolism and cartilage loss. It appears that a tight control, both in terms of timing and magnitude, is essential not only to preserve homeostasis but even to induce tissue regeneration. For instance, Yuasa et al.[46] demonstrated how controlled and temporary activation of β catenin signaling in adult mice led to an initial reduction of extra-cellular matrix (ECM), followed by chondrocyte proliferation and thickening of the articular cartilage.[46] Even more strikingly, although more remote from the context of joint disease, Kawakami et al.[49] demonstrated that although WNT signaling is essential for the capacity of some species (i.e., axolotl or Xenopus tadpoles) to regenerate entire limbs, it was sufficient to slightly modify the spatiotemporal distribution of WNT-β catenin activation to afford the chick embryo with the capacity to regenerate an entire limb.

In the clinical context of joint disease and regeneration, the complexity of Wnt signaling and its potential downstream effects may offer the opportunity to target catabolic effects while preserving the homeostatic ones. Nalesso et al.[50] demonstrated that WNT-3A drives chondrocyte proliferation through activation of the β catenin pathway and loss of differentiation through activation of CaMKII. Therefore, targeting CaMKII specifically allowed enhancement of differentiation without affecting proliferation. Better understanding of the downstream signaling mechanism and its regulation will be essential to target only the pathogenic effect of these pleiotropic signaling pathways in cartilage, bone, and the osteochondral junction.

### Growth Hormone/Insulin-like Growth Factor Axis

Other targets besides skeletal developmental pathways are activated by signaling molecules that also play critical roles in postnatal joint tissue homeostasis and turnover. These proteins/pathways can be regarded as potential postnatal "anabolic" agents that contribute to the restoration of joint homeostasis. In this regard, the growth hormone (GH)/insulin-like growth factor (IGF) axis appears to be of interest. IGF-1 has been reported to be critical in the maintenance of the homeostasis of articular cartilage explants ex vivo.[51] Further evidence of its anabolic effect in in vivo models has led to the early clinical development of intra-articular treatments with IGF-1 in knee OA, although reports of clinical trials are awaited. Furthermore, it was reported that systemic administration of GH in horses may be beneficial to joint/articular cartilage biology because it increases IGF-1 levels in synovial fluid.[52] Improved formulations of GH have been explored to improve the duration and effect size in synovial joints.[53] Some suggestions exist of a relationship between levels of IGF-1 and OA, further suggesting a potential benefit of targeting the GH/IGF-1 axis, particularly in OA. However, data thus far are inconclusive, and further systematic analysis of the hypothalamic-pituitary axis, including GH, IGF-1, and somatostatin, is required.[54]

As for all growth factor technology, in particular for the major signaling pathways previously mentioned, further studies are needed to address critical issues such as the relevant genetic background of the patients, stage of the disease process, and tissue specificity to restrict an effect to the targeted tissues, thereby avoiding systemic adverse effects.

## Stem Cell Niches

Stem cells persist in adult life to safeguard tissue maintenance and regeneration. They have the capacity to self-renew (that is, to produce more stem cells), thereby preserving a constant pool of stem cells, and they have the capacity to differentiate to replace the mature cells that are lost to physiologic turnover, injury, disease, or ageing. Self-renewal and differentiation are regulated by stem cell intrinsic factors and signals from the surrounding microenvironment in which the stem cells reside, called the "stem cell niche."

Stem cell niches have been described for a number of tissue types such as the hair follicle, intestine, and bone marrow.[55,56] In bone marrow the niches of hematopoietic stem cells (HSCs) have received considerable attention, and the understanding of HSCs has led to refinements of bone marrow transplantation in hematology. The HSC niches include the endosteal niche, where HSCs are in close contact with osteoblasts residing at the bone surface of the trabeculae, and the perivascular niche, where the HSCs are found close to the sinusoids in the bone marrow.[44]

Mesenchymal stromal/stem cells (MSCs), which are derived from bone marrow and connective tissues, including the synovium, have the ability to undergo lineage specification into chondrogenic and osteogenic cells in vitro, and to some extent also in vivo when combined with proper biomaterials and/or growth factors. Therefore, MSCs are of interest for their potential clinical use for joint tissue repair.

The joint environment is rich in progenitor/stem cells, but our understanding of their anatomic location in apposite niches and the molecular regulation of their functions remains limited. The lack of specific cell-surface markers has hindered the direct identification of the so-called MSCs in their native tissues. In bone marrow, MSCs collect in perivascular areas, where they are in close proximity to HSCs and contribute to maintaining their quiescence.[57]

Evidence is growing that pericytes may be the native cells of the ex vivo MSCs.[58] Pericytes are located on the abluminal side of small blood vessels and are in close connection with the endothelial cells of the vessels. The proximity to vessels would allow MSCs to enter the bloodstream and migrate to sites of injury,[59] but it is not clear to what degree this happens and if this phenomenon has clinical relevance. However, the notion that cells with MSC

characteristics are derived from pericytes is challenged by the retrieval of MSC-like cells in articular cartilage,[60-62] notoriously an avascular tissue. Thus pericytes may not be the only source of MSCs, and such a relationship is likely to be tissue specific and context dependent. It also must be noted that the term *pericyte* is an anatomic description of a cell that is abluminal and that its developmental origin is not clear. It is likely that, rather than having a common ancestor, pericytes have distinct ontogeny and biologic properties that are related to their tissues of residence. Cell lineage tracing experiments, which are increasingly feasible with modern technologies and detection systems, will shed light on these unresolved issues related to the in vivo nature of the native MSCs in the natural environment of their intact tissues.

Recently a double nucleoside labeling scheme in a mouse model of joint surface injury allowed the identification in the adult synovium in vivo of a population of label-retaining slow-cycling stromal cells with an MSC-like phenotype, which proliferated and differentiated into chondrocytes after injury, hence displaying typical properties of MSCs.[63] In synovium, MSCs are located in two niches: a niche in the lining layer and a perivascular niche in the sublining tissue, with the latter apparently distinct from pericytes. In these two niches, MSCs could have distinct functions, but a hierarchy remains to be demonstrated (Figure 7-3). Furthermore, MSCs in synovium is a common denomination but could reflect a co-existence of functionally distinct cell subsets.[63] The developmental origins of MSCs in the adult synovium are not known. They could in part derive from the embryonic joint interzone, as lineage tracing studies suggest.[40,64] Of note, some of the cells of the synovial lining and the superficial layer of the articular cartilage not only share a common origin from the embryonic joint interzone[40,64] but also contain cells displaying similar features, such as the ability to produce lubricin, a critical component of synovial fluid that participates in the lubrication of synovial joints.[65] Mesenchymal progenitor cells are thought to reside in the superficial zone of the articular cartilage because they display functional properties of stem/progenitor cells after isolation and culture expansion.[62] However, thus far there is no evidence that cells residing in the superficial layer are professional stem/progenitor cells with the specific function to remodel and regenerate the articular cartilage, thereby explaining the poor intrinsic repair capacity of the cartilage.

An understanding of the native MSCs and how signals at the niche sites are orchestrated toward joint homeostasis, remodeling, and repair will be essential to provide guidance regarding clinical applications that use cell-based approaches. The restoration of a functional niche will safeguard durable repair by ensuring lifelong replacement of mature cells. An exciting prospect is the pharmacologic targeting of MSCs and niche repair signals to promote joint surface repair and influence outcomes of joint disorders such as OA, with the ultimate goal of restoring joint homeostasis.

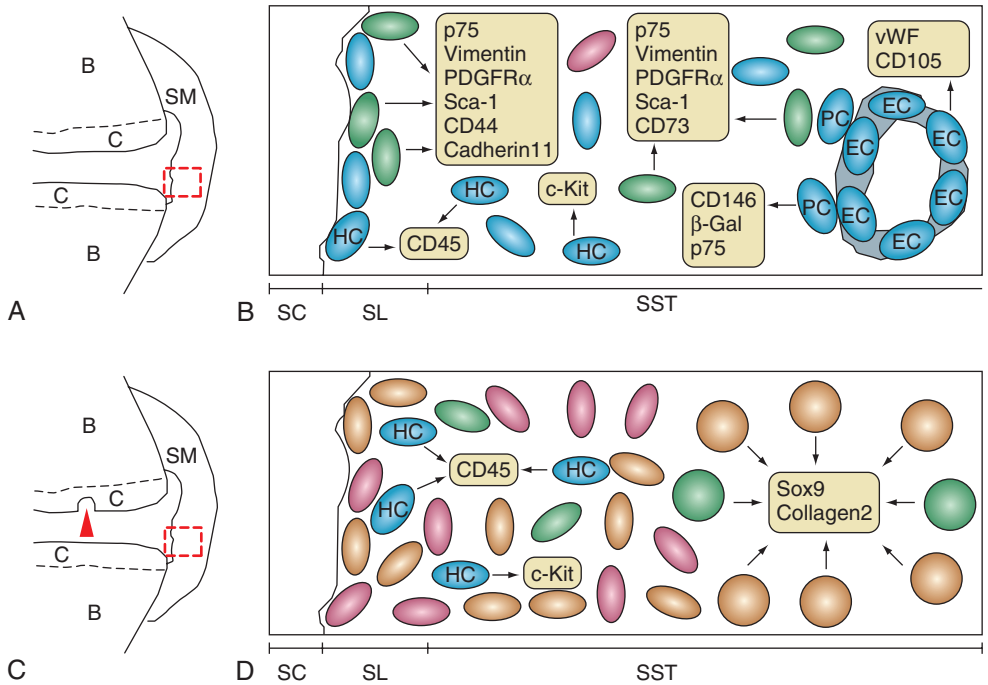

**Figure 7-3** Schematic representations of mesenchymal stem cells (MSCs) and their niches in synovium identified in mice using a double nucleoside analogue cell-labeling scheme.[76] **A**, Schematic drawing of an uninjured control synovial joint. **B**, Details of the dashed box in **A**, showing cell populations in the synovium of uninjured joints. Iododeoxyuridine (IdU)-retaining cells *(green)* were located in both the synovial lining (SL) and the subsynovial tissue (SST). Subsets of IdU-positive cells displayed an MSC phenotype. IdU-negative cells *(blue)* included hematopoietic lineage cells (HC), endothelial cells (EC), pericytes (PC), and other cell types of unknown phenotype. **C**, Schematic drawing of a synovial joint 12 days after articular cartilage injury in mice *(arrowhead)*. **D**, Details of the dashed box in **C**, showing cell populations in the synovium. Proliferating cells were detected in both the synovial lining and the subsynovial tissue and were either double positive for IdU and chlorodeoxyuridine (CldU; *orange*) or single positive for CldU *(red)*. Subsets of cells positive for IdU and CldU and cells positive only for IdU *(green)* expressed chondrocyte lineage markers. The boxed areas in **B** and **D** show cell phenotypes. ## Targeting Homeostasis of the Joint

In the resting condition, articular cartilage has an extremely low rate of turnover. For instance, the half-life of type II collagen has been estimated as being around 117 years,[66] and articular chondrocytes are all essentially in the G0 of the cell cycle. After acute traumatic injury, however, chondrocytes deploy strong adaptive responses that ultimately result in a coordinated sequence of activation and chemotaxis of progenitors within the cartilage itself and in other joint tissues, along with cell proliferation and matrix turnover. In a number of cases, such adaptive responses are sufficient to repair damage and re-establish homeostasis.[15,16] However, if the injury exceeds the adaptive capacity or if the adaptive responses are hampered in some way, cartilage loss leads to OA and ultimately joint failure. In OA the "injury" (i.e., excessive mechanical load) is continuous, and no immediate loss of tissue occurs. In such a situation the homeostatic responses are more subtle and are heralded by the upregulation of the transcription factor SOX9 and its direct targets, type II collagen and aggrecan,[67-69] as well as a limited degree of chondrocyte proliferation. It is interesting to notice that such types of homeostatic responses persist even at late stages of OA.[70-74]

### Cellular and Molecular Mechanisms of the Homeostatic Response

The sequence of events that leads to an adaptive response in cartilage is difficult to study in OA, which is a slow-progressing disease, but such study has been facilitated by the development of in vitro and in vivo models of acute injury. The first evidence of adaptive responses consisting of chondrocyte proliferation and new deposition of ECM dates back nearly one century (reviewed in reference 6). More accurate molecular analyses have identified several other components that are amenable for targeting. These components include an immediate molecular response, the activation and attraction of progenitors, breakdown of the residual mature ECM, the filling of the defect, tissue patterning, and, finally, tissue maturation—which, in humans, can take several years. In the entire joint, inflammation is an integral part of a natural response to injury, providing molecular signals and cascades that are likely to have distinct context and tissue-specific beneficial or detrimental effects. Studies aimed at teasing apart the "good" from the "bad" pathways will help modulate repair processes and restore/maintain joint homeostasis.

In therapeutic terms, therefore, it may be possible to target any of these phases, but it is likely that a stratified approach will be necessary to ensure efficacy and consistency. Such an approach will start with the understanding of which step of the homeostatic response has failed in groups of individual patients so that the appropriate approach will be targeted to the appropriate patients (Figure 7-4).

**Immediate Molecular Response.** Scarification of the articular cartilage in vitro or in vivo induces a strong early molecular response dominated by the activation of signaling pathways known to play important roles in embryonic skeletogenesis.[14,75-80] Although this response is very rapid and transient, it primes a cascade of downstream steps. Probably the best known pathways involved in this phase are the WNT, FGF, and TGF-β/BMP pathways, which are discussed elsewhere in this chapter. It is important to say here, however, that although proof of concept for efficacy with each of these pathways has been provided in some way in different models, the often disparate functions that these pleiotropic signaling molecules have in each different cell type remain a challenge. Tissue-targeted treatments will be of importance, including the use of novel smart delivery systems to confine the signaling domain of such powerful morphogens and avoid off-target effects.

**Activation and Attraction of Mesenchymal Progenitors.** It has been suggested that mesenchymal progenitors are implicated in the repair of joint surface defects, including those derived from bone marrow,[81] the synovial membrane, and the cartilage itself.[61-63,82-84] However, the origin and lineage of the cells that contribute structurally to cartilage regeneration is still uncertain and the object of intense research. Yet the understanding of the pathophysiologic mechanisms driving stem cell commitment and differentiation is paving the way to promising therapeutic interventions that exploit homeostatic mechanisms. In 2012, Johnson et al.[15] identified a small compound, kartogenin, which, by interacting with filamin A, regulates the

activity of the CBFβ-RUNX1 transcriptional program in bone marrow–derived mesenchymal cells, inducing their chondrogenic differentiation. The delivery of kartogenin to mice subjected to instability-induced OA improved pain and resulted not only in the arrest of disease progression but even in regeneration of the cartilage tissue to some degree. Although kartogenin could induce chondrocytic differentiation of bone marrow stromal cells in vitro, it is not clear whether this effect on bone marrow stromal cells contributed to the chondroprotective effect of kartogenin in vivo. In fact, recent data show that kartogenin could support harmonious skeletal growth, joint morphogenesis, and the resorption of the interdigital mesenchyme, which are otherwise stunted in ex vivo cultures of embryonic mouse limbs.[85] These effects were associated with the activation of several signaling pathways and in particular of the TGF-β pathway. The effect of kartogenin is likely to be more complex than the simple capacity to induce chondrogenic differentiation of MSCs.

**Patterning and Differentiation.** After the joint surface defect is filled with mesenchymal cells, the repair tissue needs patterning to acquire the final architectural structure, with a properly layered cartilage and osteochondral junction. Interestingly, both morphologically and molecularly, the repair tissue in an osteochondral defect resembles the epiphysis of a developing skeletal element, with flat cells at the surface, then chondrocytes in different stages of maturation, and hypertrophic chondrocytes at the boundary with the bone front.[86] With time the bone front advances and, for successful repair, must stop to leave a layer of permanent stable articular cartilage. Failure of this patterning process results in failure of repair both in animal models[87,88] and also in humans, where excessive advancement of the bone front can lead to intra-articular osteophytes after surgical procedures such as bone marrow stimulation by microfracture.[89] Clearly such sophisticated coordination of differentiation requires a tight control and positional information so that each cell "knows where it is and what to do" within the repair tissue.

PTHrP signaling during embryonic development of the skeletal elements contributes to the positional information and regulates the rate of differentiation of the chondrocytes through the epiphysis, preventing precocious or ectopic hypertrophic differentiation and endochondral bone formation.[90-93] The PTH/PTHrP receptor PPR is hardly expressed in normal cartilage but is strongly upregulated in the intermediate layers of repair cartilage, just above the bottom layer of hypertrophic chondrocytes[86] and in osteoarthritic cartilage. Because hypertrophic differentiation of articular chondrocytes is not only a feature of OA but also drives cartilage breakdown[94,95] and PTH/PTHrP signaling is known to delay hypertrophy, Sampson et al.[16] tested whether a truncated form of human recombinant PTH currently used in the clinic for osteoporosis could improve the outcome of OA in mice. Indeed, human recombinant PTH could not only stop cartilage breakdown but also induced a regenerative effect. Unfortunately, the doses required to achieve this impressive effect in mice were very high and induced osteopetrosis. A restriction of the signaling domains to the tissue of interest is therefore required before this approach can be used in the clinic. Another caveat is that this study cannot discriminate between the effects on cartilage and those on the bone. In this context, it is noteworthy that strontium ranelate, another compound used as an anabolic agent in osteoporosis, was also able to reduce the rate of joint space narrowing and to improve symptoms in patients with OA.[96] Similar results were replicated in a rat and a dog model of instability-induced OA.[97,98]

## EXTRINSIC REPAIR: CURRENT THERAPEUTIC INTERVENTIONS

Cell-based therapies and TE for joint repair have entered clinical practice with long-term follow-up data. At an earlier stage of development, the use of embryonic stem cells, induced pluripotent stem cells, or adult stem cells (such as MSCs) have shown promising pre-clinical and early clinical safety and efficacy data.

The mechanisms through which the cellular therapies and combination products contribute to tissue repair are multiple and involve direct engraftment, proliferation, and differentiation to tissue-specific cell types but also include paracrine actions such as the secretion of growth and differentiation factors that enhance the local tissue response.[99] In addition, adult stem cells may have immunomodulatory properties, which have been clinically explored in graft-versus-host disease and autoimmune diseases.

### Joint Surface Defects

A variety of articular cartilage repair techniques have been developed, typically for the treatment of (sub)acute focal joint surface defects that are often associated with excessive joint loading, either as a result of high-impact trauma or cumulative low-impact repetitive overload. Joint surface defects are classified as chondral or osteochondral. Joint surface lesions can extend to the subchondral bone (osteochondral defects) or be limited to the cartilage (chondral defects). Most chondral defects do not reach to the bone (partial thickness), and only about 5% are full thickness[100]; nevertheless, because most partial-thickness lesions are debrided at the time of surgery to full thickness, including the removal of the calcified layer (Figure 7-5), repair strategies focus on the treatment of full-thickness defects. The best established cell-based technology for the treatment of these lesions is autologous chondrocyte transplantation and its several variations.

#### Autologous Chondrocyte Transplantation

Regeneration or repair of symptomatic articular cartilage defects has been at the forefront of regenerative medicine ever since 1994 when Brittberg et al.[101] reported a remarkably good clinical and structural outcome using a procedure called autologous chondrocyte transplantation/implantation (ACI). Briefly, cell populations were prepared by enzymatic release from a biopsy specimen of articular cartilage taken from an unloaded area in the symptomatic joint. The chondrocytes were subsequently expanded in vitro, and after six to eight population doublings, they were reimplanted in the joint surface defect under a periosteal flap taken from the tibia from the same patient. This procedure was then followed by a long rehabilitation period to reach its optimal outcome at 18 to 24 months. This high-profile publication

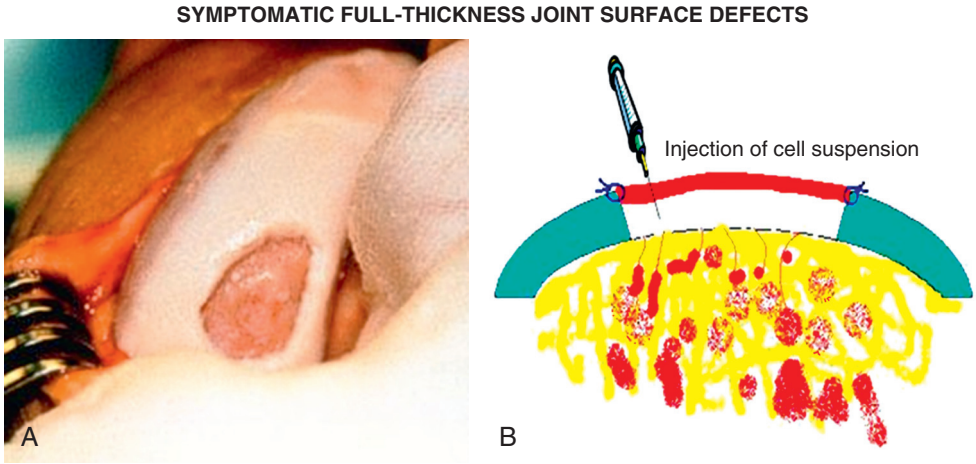

**Figure 7-5** **A,** View at open knee surgery of a large full-thickness articular cartilage defect. Note the sharp borders of the lesion after surgical debridement. **B,** A cell suspension, such as autologous chondrocytes, is injected beneath a periosteal flap or membrane sutured on the joint surface and sealed with fibrin glue to prevent leakage.

attracted considerable interest and triggered a wave of basic, translational, and clinical research in the field. It also evolved quite quickly in 1997 in the marketing of Carticel, an autologous cell product for the repair of symptomatic condylar defects of the knee, by Genzyme Corporation (Cambridge, Mass.).

Progress has been made since then with studies aiming to improve and standardize the autologous chondrocyte preparation (the cell product), the development of other delivery systems for the chondrocytes and the replacement of the periosteal flap with a membrane of diverse composition, and a series of clinical studies. After a number of mostly open studies with diverse outcomes (for a review see van Osch et al.[102]), a study by Knutsen et al.[103]—the first multicenter, prospective, randomized trial—failed to demonstrate that ACI was superior to microfracture, a technique mostly considered to be the standard of care for small (<2 to 3 $cm^2$) symptomatic joint surface defects. Microfracture is a bone marrow stimulation procedure and is based on the puncturing of the subchondral bone plate into the bone marrow, the generation of a blood clot containing precursor cell populations derived from the subchondral bone marrow, and the spontaneous transformation of the repair clot into a fibrocartilaginous repair tissue.[104] Microfracture is clearly associated with a clinical benefit and a filling of the joint surface defect with repair tissue, but it is generally accepted that this repair is not durable, resulting in a consistent decline in clinical outcome over the long term.[105,106] It is the aim of ACI to repair the cartilage defect with better quality tissue, mostly hyaline cartilage with tissue characteristics matching those of the neighboring tissue, thereby resulting in improved long-term outcomes (Figure 7-6). Although the study by Knutsen et al.[103] did not indicate clinical superiority of ACI over microfracture, there were some indications that good structural repair was associated with durable clinical outcome.[107]

Subsequently, progress was made by improving the manufacturing process of the chondrocyte preparation. Indeed, in Europe, an autologous chondrocyte cell product called ChondroCelect (TiGenix, Leuven, Belgium) was developed and obtained the first cellular product central registration

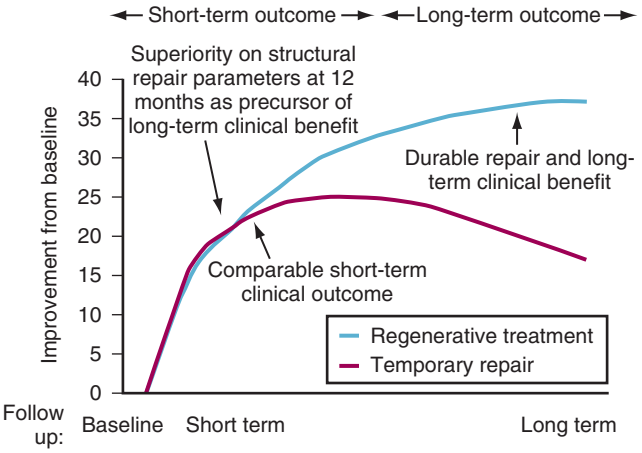

**Figure 7-6** The expected difference between repair of a joint surface lesion by a mechanism of scarring versus true tissue regeneration. Both treatment approaches (e.g., microfracture and autologous chondrocyte transplantation [ACI]) show clinically equal benefit at the short term, but repair tissue closer to the native tissue is seen with a regenerative approach (e.g., as seen in ACI). Long-term outcomes are more durable using regenerative approaches, in some cases leading to cure.

by the European Medicines Agency under the new advanced therapy medicinal product regulation. In a prospective randomized multicenter study, ChondroCelect, defined and characterized as a cell population capable of making stable cartilage in surrogate in vivo models and quality controlled through use of biomarkers, was shown to result in structurally superior repair tissue at 12 months after implantation compared with microfracture, with a superior clinical outcome at 3 years, but noninferiority in the overall population at 5 years.[108] The 5-year data demonstrate a clinically relevant superior outcome in the subpopulation of patients with relatively recent lesions (<3 years). This prospective, well-designed landmark clinical trial supports the concept that an improved understanding of the underlying biology and the consequent optimization of the manufacturing process lead to improved clinical outcome. In addition, stratification of patients will have a major impact on

the potential for regenerative medicine approaches to move forward successfully to proper clinical use in daily practice.

The surgical delivery of these therapies is another important factor that requires standardization. In this regard, ACI is becoming a more easily controllable arthroscopic procedure. A recent study that used an arthroscopic approach reported a statistically better clinical outcome for matrix-applied autologous chondrocytes after 2 years when compared with microfracture.[109] Interestingly, in this case, structural repair as assessed by MRI and biopsy was not different from microfracture at 2 years.

Although still open for debate with respect to long-term clinical durability, there is a consensus that ACI, and variations thereof, can be considered a regenerative treatment with good structural and clinical outcome. Long-term clinical outcomes have been reported and indicate a good durability of the treatment in a substantial number of patients over periods exceeding 10 years.[110]

Importantly, the data indicate that the outcome is superior to standard care if the "proper" patients are treated. Positive predictors of good outcome include the age of the patient, the location of the defect, early intervention (<3 years after becoming symptomatic), good quality of chondrocytes, well-trained surgeons, adherence to rehabilitation protocols, and no signs of OA (as defined by the Kellgren II grading scale on standard radiographs).[111] Cost-effectiveness will certainly improve if the treatment is also shown to prevent the progression toward (early) OA, but these data are not yet available.

### Stem Cell–Based Approaches

The next wave of development is the use of progenitor cell populations, or the so-called MSCs, in particular in an allogeneic approach.

MSCs are easy to isolate, expandable in culture, and chondrogenic, and therefore they are attractive alternatives to chondrocytes in an ACI procedure. These properties of MSCs would allow upscaling and generation of large quality-controlled batches, thus circumventing the limitations and patient-to-patient variability of autologous cell protocols. For these reasons, the use of MSCs for joint surface repair is intensively sought[112-114] and has been explored in humans.[115] These studies have shown promising results, with cartilage formation and endochondral bone formation restoring the bone front. However, uplift of the bone front at the expense of the articular cartilage has been commonly observed[87] and has its clinical equivalent in intralesional osteophyte formation in patients after microfracture.[116] This "side effect" appears to be less frequent in patients treated with ACI,[117] suggesting that an imprinted memory of articular chondrocytes could preserve the normal thickness of the repair cartilage and limit the advancement of the bone front. This finding points to a need, when using MSCs, for strategies to enhance stable cartilage properties and reduce fibrous tissue and hypertrophic cartilage formation.

Another important area of investigation is the tissue source of MSCs. Adult bone marrow MSCs are leading candidates for use in the repair of cartilage defects and other skeletal tissues such as bone defects.[118] However, MSCs from bone marrow appear to have a high propensity to cartilage hypertrophy and bone formation[119,120] and may not be the ideal chondroprogenitors for the repair of articular cartilage. In this regard, superiority of MSCs from synovial membrane for cartilage formation in vitro when compared with MSCs from other tissue sources, including bone marrow and periosteum, has been reported.[82,121,122] Promising data using synovium-derived progenitors have been reported in vivo, but at this point the long-term outcome of these approaches is unclear.[123,124]

The differences in chondrogenic potency of MSC populations could find their origins in the distinctive molecular programs of embryonic formation of their native tissues, because lineage tracing studies in mice demonstrated a common developmental origin of articular cartilage and synovial membrane from the Gdf5-positive cells of the embryonic joint interzone.[40,64]

The solution to the challenge of stable-cartilage formation, displaying also the very specific articular cartilage characteristics, may come from the use of chondroprogenitors isolated from the articular cartilage itself, which display the ability to maintain chondrogenic potency upon extensive culture expansion.[125] A proof-of-principle pilot study in a goat model in vivo demonstrated the apparent noninferiority of these chondroprogenitors to form a cartilage-like repair tissue in a chondral defect when compared with full-depth chondrocytes.[126] Human studies will be needed to demonstrate noninferiority of MSCs or any other stem/progenitor cell populations in clinical and structural outcomes when compared with the gold-standard articular cartilage–derived chondrocytes in ACI-like procedures.

The use of MSCs in joint resurfacing in animal models and humans reveals a variable structural outcome, ranging from hyaline-like cartilage to fibrous tissue. This finding has prompted interventions to support tissue maturation by using cartilage-promoting growth factors along with smart biomaterials.[127] However, the combination of cells, biomaterials, and morphogens would make the assessment of efficacy and toxicity more complex and the path from animal experimentation to clinical application arduous.

The use of allogeneic MSCs has shown an acceptable safety profile.[128] However, the pre-clinical data on the immunogenicity of MSCs are conflicting, and the acquired differentiated phenotype of the implanted stem cells may result in the loss of the immunologic privilege, with consequent rejection of the cells.[129,130]

Nonetheless, the use of allogeneic stem cells would allow manufacturing of large batches of stem cell products with specific clinical indications, off the shelf. Such an approach increases consistency and decreases costs of cell therapies, potentially accelerating the translational process toward routine clinical application.

### Osteochondral Repair

Whereas regeneration strategies for chondral lesions have been tested in high-quality clinical trials, the management and repair of osteochondral defects, with damage to the articular cartilage and reaching deep into the subchondral bone, remains a significant problem (for a review see Nukaravapu and Dorcemus[131]). Indeed, both the articular cartilage and subchondral bone need to be repaired with

restoration of a new calcified layer and tidemark, fully integrated and aligned with the neighboring tissue. The major challenge lies in the development of biologically educated regenerative treatments for osteochondral defects without resorting to prostheses. Prosthetic joint resurfacing has a limited life span, and revisions can be surgically challenging and are not ideal in younger patients with higher functional expectations.

The most common clinically used methods to treat osteochondral defects include debridement, bone marrow stimulation techniques such as microfracture, and the use of osteochondral allografts. Although they have shown some short-term positive results, the approaches taken are suboptimal and not curative and face serious drawbacks. Most of these treatments address only symptoms, and the use of allografts for larger osteochondral defects involves risks for immune rejection, disease transmission, and issues related to donor site morbidity and tissue availability. Currently, for osteochondral lesions bigger than 2.5 $cm^2$, the most commonly used clinical restorative method is ACI, using surgical variations with a so-called "sandwich approach." However, the results are mixed and are neither robust nor predictable.

Several scaffold strategies have been developed and evaluated for osteochondral repair requiring bone, cartilage, and bone-cartilage interface regeneration. Indeed, one of the main aims in the development of repair strategies for osteochondral applications is to closely mimic the native osteochondral tissue gradient structure. The challenge is to create distinct but seamlessly integrated layers intended to repair articular cartilage, calcified cartilage, and bone.[132] Therefore, osteochondral TE research has been evolving from cell-based therapies to single-layer scaffold repair, followed by biphasic constructs, and ultimately to multiphasic constructs. Classically, biphasic materials entailing a cartilaginous layer and bone part have been described in several studies and have shown some success.[125,133] Among biphasic scaffolds, hybrids can be prepared by filling soft hydrogels into hard sponges. As an example of this approach, Wang et al.[134] successfully developed a composite construct consisting of a polylactide-co-glycolide (PLGA) sponge filled with fibrin gel, bone marrow MSCs, and TGF-β1 for full-thickness cartilage defect restoration in vivo. In vitro and in vivo studies in a rabbit model revealed that the PLGA/fibrin gel/MSCs/TGF-β1 constructs are an appealing candidate for osteochondral restoration.[134] This type of biphasic composite construct paved the way for the use of multilayered scaffolds for osteochondral defects.

Following this progression, increasing interest is being devoted to gradient scaffolds with continuous interfaces to more faithfully mimic the natural hierarchical architecture. A clinical pilot study was performed in which a nanostructured, three-layered, collagen-hydroxyapatite construct was applied for the treatment of chondral and osteochondral lesions of the knee joint. This system was able to induce in situ regeneration via stem cells coming from the surrounding bone marrow in an innovative cell-free approach translatable to clinical practice.[135] In a sheep model, similar trilayered magnesium-hydroxyapatite-collagen type I composites were able to promote bone and cartilage tissue restoration by inducing the selective differentiation of resident progenitor cells, such as bone marrow–derived and/or synovium-derived cells, to osteogenic and chondrogenic lineages. Thus this approach indicates the potential of a suitable hybrid scaffold matrix that can direct and coordinate the process of bone and hyaline-like cartilage regeneration.[135] Other studies, also using biomimetic multilayered scaffolds, focused more on the development of a tidemark (intermediate layer). For example, hydroxyapatite/collagen bio-hybrid composites, prepared via a biologically inspired mineralization process, supported selective cell differentiation toward both osteogenic and chondrogenic lineages. Finally, continuous gradients in both material and bioactive signals take us one step further in scaffold complexity to achieve a high degree of mimicry. Continuous gradients can be added into hydrogels with incorporation of drug delivery systems (e.g., drug-loaded microspheres). As an elegant example of this approach, Wang et al.[134] incorporated recombinant human (rh) BMP-2 and rhIGF-1, microencapsulated in PLGA and silk microspheres, to form continuous concentration gradients in alginate gels and silk sponges. The combination of growth factors in different carrier systems enabled spatial control of the growth factors' distribution and temporal control of their release.

Although the use of tailored scaffolds associated with suitable factors and proper stem cell technology appears to be a more advanced TE strategy, the complexity intrinsic to such scaffolds presents a considerable set of technological, regulatory, and financial challenges on the way to routine clinical application.

## Bone Regeneration

The most promising field to explore the full potential of regenerative medicine approaches in musculoskeletal medicine is bone regeneration. Bone already has a remarkable potential to heal postnatally, which indicates that all the necessary tools are available to obtain full tissue repair, without any tissue scarring, and thus also to obtain tissue integration and remodeling. We should thus understand how nature heals bone fractures postnatally and subsequently mimic these repair processes when bone healing goes wrong, such as in delayed healing and nonunions, or in the repair of large bone defects such as avascular necrosis or after resection of bone tumors.

The standard of care in bone repair is the use of autologous bone grafts, which are typically obtained from the iliac crest. However, important developments have moved the boundaries in the field of bone engineering and include the development and improvement of biomaterials and new technologies in the design and production/manufacturing of these new biomaterials. It is not within the scope of this chapter, but suffice it to say that the spectrum of the smart biomaterials for bone engineering is vast, and recent progress has resulted in the production of resorbable and osteoconductive products, with some even displaying osteoinductive properties.[136] These latter characteristics have been obtained by coating biomaterials with bioactive factors, including growth factors such as the BMPs.[30] BMP devices have not only led to more robust and predictable outcomes in spine fusion but most importantly have demonstrated that recapitulation of embryonic tissue formation processes can lead to successful bone healing postnatally, as well as in long bone healing.

Despite all this progress, we still are not capable of healing large long bone defects in patients. In view of this, we and others believe that a combined implant incorporating smart and resorbable biomaterials, stem/progenitor cell populations, and growth factors will be required.[137] Failure of bone healing is typically associated with the lack of vascularization and the proper precursor cell populations not being available. Therefore, the generation of tissue-engineered viable implants will need to provide tools to enhance vascularization of the implant and promote cell survival to come to full fruition. Thus far, the results of the so-called combination products (scaffold and cells, eventually enriched with growth factors) have been somewhat disappointing. Lack of an underlying scientific basis for the design and manufacturing of these implants is probably responsible for a large part of this disappointment. Therefore, a bio-inspired model called developmental engineering was proposed and extensively described.[138,139] Recent publications indicate that this approach may be more successful than the traditional cells on the scaffold trial-and-error approach.[120] Most importantly, good prospective multicenter clinical trials are ongoing (see the World Health Organization International Clinical Trials Registry Platform and the European Union Drug Regulating Authorities Clinical Trials [EUDRACT] database) to better establish the clinical relevance of the different bone TE strategies. They include the direct percutaneous injection of expanded bone marrow MSCs in long bone nonunions, both autologous and allogenic, and the implantation of bone marrow–expanded MSCs with a bone substitute (hydroxy apatite/tricalcium phosphate carrier) in long bone nonunions. The development of some of the more complex TE techniques is raising further challenges, also with regard to the manufacturing of those products.

## Regeneration of Other Joint-Related Structures

Lesions of the articular cartilage are often associated with damage of other joint structures such as menisci, ligaments, and tendons, which need to be addressed to restore joint homeostasis. An attractive holistic approach to joint regeneration could be intra-articular delivery of MSCs. The injection of bone marrow MSCs in a hyaluronan suspension in a goat model of OA obtained by medial meniscectomy and anterior cruciate ligament resection resulted in a meniscus-like neo-tissue formation that provided protection from OA progression.[140] Similar data were obtained with intra-articular injection of synovial membrane–derived MSCs that promoted meniscus regeneration in a rat model.[141,142] Recently, a proof-of-concept phase I/II clinical trial assessed the safety and efficacy of intra-articular injection of autologous adipose-derived MSCs for knee OA. After a phase I study consisting of three dose-escalation cohorts with three patients each, phase II included nine patients receiving the high dose ($1.0 \times 10^8$ MSCs). The primary outcomes were the safety and the Western Ontario and McMaster Universities Arthritis Index (WOMAC) at 6 months; secondary outcomes included clinical, radiologic, arthroscopic, and histologic evaluations. The intra-articular injection of MSCs into the osteoarthritic knee improved function and pain of the knee joint without causing adverse events and reduced cartilage defects by regeneration of hyaline-like articular cartilage.[143] Reports from other ongoing clinical trials are awaited.

### Menisci

The menisci have a poor healing potential largely because their vascularity is restricted to the external third of the tissue.[144] A subtotal or total meniscectomy is now rarely performed in view of the high risk of OA development, but a partial meniscectomy can be necessary in symptomatic patients. The use of a cell-free biomaterial to replace part of the meniscus relies on repopulation of the scaffold by the host cells from the joint environment. The collagen meniscus implant (ReGen Biologics, Franklin Lakes, N.J.) was the first regenerative method applied to meniscal tissue in clinical practice.[145-147] Noncontrolled case series have reported pain relief and functional improvement at 10-year follow-up.[148] Despite the wide clinical use, no randomized controlled trial supports the use of meniscal implants in routine clinical practice. The Actifit (Orteq Ltd, London) meniscus implant is a polyurethane-polycaprolactone–based synthetic meniscal substitute for partial meniscal defects,[149] but evidence about its safety and effectiveness is awaited.

Meniscal transplantation is a valid short-term option in selected patients with symptomatic, totally meniscectomized, aligned knees.[150] Limitations of this procedure include tissue availability, graft sizing, and risks of immune reaction and disease transmission. Fixation of the allograft also remains a significant challenge.

Regenerative medicine holds the potential for restoring anatomy and function of meniscal fibrocartilage. Several cell types have been assessed in meniscal TE, including meniscal cells from the meniscectomized meniscus itself; articular, costal, and nasal chondrocytes; MSCs; and embryonic stem cells (reviewed in reference 151). They are seeded onto biomaterials, both natural and synthetic, which are anticipated to be biocompatible, biodegradable, bio-instructive (promoting cell differentiation and cell migration if cell free), biomimetic (mimicking architecture and biomechanics of the native meniscus), resistant to mechanical forces, porous (allowing diffusion of nutrients), and user friendly for the surgeon. Natural materials such as small intestine submucosa[152] and acellular porcine meniscal tissue[153] have high biocompatibility but do not allow varying structure geometry and adequate initial mechanical properties. Isolated tissue components such as collagens and proteoglycans allow generation of custom-made scaffolds with high biocompatibility.[154] However, these scaffolds usually have low biomechanical properties and are characterized by rapid biodegradation, and they are not sufficiently long to be completely replaced by the newly formed tissue.[151] Synthetic polymers (e.g., polyglycolic acid [PGA] and polylactic acid [PLA]) can be manufactured in custom-made shapes and with custom-made porosity and biomechanical properties, and the use of biopolymers such as silk fibrous protein has been explored to improve biocompatibility and biodegradability.[155] A possible solution is to couple the high biocompatibility of natural polymers with the superior mechanical strength and ease of being tailored of the synthetic polymers.[156]

A fascinating strategy entails the use of hydrogel materials,[157] because their semiliquid nature allows engineering

anatomic geometries derived from medical imaging such as computed tomography.[158]

MSCs seeded onto a hyaluronan-collagen–based scaffold were recently used to repair a critical-size meniscal defect in an orthotopic rabbit model.[159] Although menisci repaired with the engineered tissue demonstrated a significantly better regeneration than did those repaired with the cell-free scaffold, the cell-loaded implants did not restore a normal meniscus.[159] Uncultured bone marrow cells in hyaluronan-collagen composite matrices stimulated the development of integrated meniscus-like repair tissue,[160] suggesting the feasibility of a one-step approach for partial meniscus TE.

Total meniscus TE offers an alternative to allografts to overcome the problems of availability, graft sizing, and immune reaction. The implantation of a PGA-PLGA scaffold seeded with allogeneic meniscal cells in a rabbit meniscectomy model resulted in a tissue histologically resembling normal meniscus.[161] Similar promising results were reported with a hyaluronic acid/polycaprolactone material seeded with expanded autologous articular chondrocytes in a sheep orthotopic model.[156] Mandal et al.[155] reported the development of a TE meniscus based on a tri-layered silk fibrous protein scaffold seeded with human culture-expanded fibroblasts in the outer part and chondrocytes in the inner part. The same authors reported the use of such trilayered scaffold seeded with human culture-expanded MSCs, showing native-like tissue structure and compressive properties in vitro.[162]

Despite the extensive pre-clinical and clinical investigations, none of the current strategies has demonstrated regeneration of a functional, durable meniscal tissue and full re-establishment of knee homeostasis. Advances in cell biology, biomaterial science, and bioengineering (e.g., bioreactors) have the potential to drive meniscus regeneration into more clinically relevant and feasible strategies.

### Tendons

Common tendon injuries are tears of the rotator cuff, Achilles tendon, and flexor tendons of the hand. At present, they are treated with surgical repair and/or conservative approaches. Unfortunately, current treatment strategies fail to restore the functional, structural, and biochemical properties of the repaired tendons compared with native tendons. Tendon repair has been attempted with platelet-rich plasma, an autologous source of concentrated growth factors relevant to wound repair.[163] Numerous growth factors have been shown to play a role in tendon healing, but the application of growth factors such as IGF-1, TGF-β, or GDF-5 (BMP-14) to clinical tendon repair remains challenging.[164]

In cases of severe tendon injury, surgical treatments may be used to repair or replace the damaged tendon with autografts, allografts, xenografts, or prosthetic devices. The unsatisfactory clinical outcomes with high failure rates[165] have prompted the development of TE strategies. With regard to the choice of cell types to use, the harvest of autologous tenocytes may cause secondary tendon defects, and thus dermal fibroblasts have been considered because they are easily accessible and do not cause major donor site morbidity.[166] In a recent clinical trial, an injection of dermal fibroblasts suspended in autologous plasma improved the healing of refractory patellar tendinopathy.[167] MSCs are another promising cell source for tendon TE. In a rabbit model, PGA sheets seeded with bone marrow MSCs enhanced mechanical strength when compared with a cell-free PGA scaffold.[168] Stem cells have also been identified in tendons.[169] Tendon-derived stem cells in fibrin glue, compared with fibrin glue alone, promoted superior tendon repair histologically and biomechanically.[170] Despite their potential advantages, the isolation of autologous cells would present the same donor site morbidities as tenocytes.

Three major categories of scaffolds are used in tendon TE: native tendon matrices, synthetic polymers, and derivatives of naturally occurring proteins. Cutting-edge processing protocols allow decellularized tendon scaffolds to maintain similar biomechanical properties compared with native tendon tissues.[171] Moreover, a number of ECM proteins and growth factors are preserved in acellular tendon,[172] suggesting potential bio-functionality of these scaffolds. Synthetic polymers such as PGA and poly-L-lactic acid have been used but have limitations, including the absence of biochemical motifs for cell attachment and the inability to regulate cell activity.[173] Scaffolds made from natural proteins and their derivatives may address these issues. Because tendon ECM is mainly composed of type I collagen, scaffolds based on collagen derivatives are highly biocompatible and exhibit superior biofunctionality by supporting cell adhesion and cell proliferation better than polyester materials.

A greater understanding of the molecular mechanisms underpinning tendon development and natural healing coupled with the advances in biomaterials and nanotechnology that allow a closer replication of the native tissues and delivery of growth factors with high spatiotemporal resolution and specificity[174] will allow tissue engineers to recapitulate tendon morphogenesis for repair. The insertion of tendons into bone remains a challenge.

Researchers are also investigating the possibility of regeneration by triggering/enhancing the natural healing response. This goal could be achieved by using off-the-shelf biomaterials capable of delivering growth factors at specified times to recruit endogenous cells and direct repair to restore native tissue anatomy and function.[175] The application of biophysical modalities such as low-intensity pulsed ultrasound[176] is also promising for promotion of intrinsic healing and improving the mechanical properties of healing tendon-bone insertions.

## REGENERATIVE MEDICINE AND TISSUE ENGINEERING IN ARTHRITIS

As we start to understand intrinsic tissue response mechanisms and attempts to counteract destructive processes by enhancing tissue repair, new therapeutic targets have been identified and targeted with "classical" pharmaceutical approaches such as the development of protein therapies and small molecules interfering with critical repair mechanisms. However, these approaches may still be far from sufficient and "too targeted," and therefore more comprehensive approaches may be needed. For this reason, cellular therapies and combination products have been explored. Indeed, cellular therapies will affect local processes in many ways as cell populations are manufactured so they deliver a

vast array of secreted signals, also called their *secretome*, which is likely to influence local disease processes and enhance repair. Conversely, it becomes clear that the microenvironment will affect the cellular products and influence what they secrete and how they interact with the environment, including their engraftment, proliferation, differentiation, and tissue integration and remodeling.[177] Therefore, for regenerative medicine and cellular therapies to be successful, particularly in disease, we need to assess and quantify the microenvironment and mutual interactions between the cell-based product and the microenvironment. This approach points toward the importance of personalized medicine, and indeed, for regenerative medicine approaches to become cost-effective and successful, identifying the patients at risk and predicting responders to treatment will be of utmost importance.

Different cellular therapeutic approaches have been investigated in chronic arthritis, with most data available on the use of adult MSCs. Proof-of-principle studies have been established for distinct indications. For inflammatory diseases such as RA and other autoimmune systemic diseases, the immune suppressive and immune modulatory effects of cellular therapies can contribute to the control of disease activity,[178] but this application is outside of the scope of this chapter.

Cellular therapies to enhance tissue repair have been explored quite extensively in pre-clinical animal models of post-traumatic OA.[140] The use of MSCs has been explored in patients with OA.[115,179-183] The mechanisms through which they can influence the disease processes in OA appear diverse as previously discussed and include the so-called trophic effects, immune suppressive effects, and anti-inflammatory effects, as well as cell engraftment and contributing to the local de novo tissue formation, leading to meniscal and cartilage repair.[141,184] Because cellular products can potentially have all these effects, properly manufactured cell-based therapies might restore joint homeostasis thereby preventing disease progression in OA.

## CONCLUSION

Regenerative medicine approaches are providing new and exciting opportunities in medicine in general and in the field of musculoskeletal disorders and diseases in particular. In orthopedics, cell-based tissue repair has entered the routine armamentarium and daily clinical practice. The development of injectable or arthroscopically implantable "regenerative biologics" will soon introduce regenerative medicine to the therapeutic options of rheumatologists. These options will include but are not limited to the repair of damaged joint surfaces, both chondral and osteochondral defects, the regeneration of difficult to heal fractured bones, the repair of damaged ligamentous structures, and the fabrication of a variety of "off the shelf" skeletal tissue structures, such as *viable* pieces of bones, ligaments, menisci, and other joint tissues. These regenerative treatments will not only be of use for post-traumatic damaged joints and skeletal tissues but also for (post)inflammatory and osteoarthritic joints.

Ultimately, the implantation of a *biological* prosthesis with the potential of full tissue integration and remodeling is a dream target, and proof of principle exists that such a prosthesis may be within reach.[185,186] To achieve this goal in a more robust and predictable fashion, we need to change our strategy, using a bio-inspired engineering approach.[138,139] We proposed the term "developmental engineering" to describe a methodology for rational and accurate design of robust, well-controlled manufacturing processes. A close interaction between the efforts of biologists and engineers will speed up TE processes.

The stage is set, and it is up to the biomedical TE community to break the boundaries toward the manufacturing of biological spare parts of the body. It is anticipated that the musculoskeletal field, and thus patients with skeletal disorders and diseases, will benefit from this approach sooner rather than later.

In spite of the advances in the field of tissue repair/regeneration in musculoskeletal conditions, these technologies are not yet in common use, and the National Health Services of several countries do not provide reimbursement. This situation is largely related to the high direct costs associated with such procedures, and cost-effectiveness remains a critical issue. A Swedish study has shown the health economic benefit of regenerative treatments when the reduction of disability, absenteeism, and other indirect costs are taken into account.[187] For those treatments to become affordable, however, a number of technological gaps still need to be filled. Some of the emerging approaches include (1) the use of heterologous cell sources such as stem cells; (2) the harnessing of the intrinsic reparative mechanisms and homeostatic pathways through the use of bioactive molecules and/or acellular devices; and (3) the use of physical intervention, such as joint distraction,[188] which, by temporarily reducing the mechanical injury, would allow reparative mechanisms to take place.

At this stage we have obtained convincing evidence that regenerative musculoskeletal medicine has the potential for long-term, possibly lifelong efficacy in patients. The challenges have been identified and described. The growing knowledge in the molecular and cellular basis of the processes that drive tissue destruction and repair, disease progression, and homeostasis is paving the path by supplying an increasing number of targets for both pharmacologic interventions, potential biomarkers, and a new generation of advanced therapeutic medicinal products.

CHAPTER 8

# Proteinases and Matrix Degradation

Yasunori Okada

**KEY POINTS**

- Proteinases are generally classified into aspartic proteinases, cysteine proteinases, serine proteinases, and metalloproteinases according to their catalytic mechanism.
- Because of the optimal acidic pH and intra-cellular localization within lysosomes, most of the aspartic proteinases and cysteine proteinases are involved in intra-cellular degradation of extra-cellular matrix (ECM) components.
- Serine proteinases and metalloproteinases are neutral proteinases and play a central role in extra-cellular degradation of ECM macromolecules.
- ECM-degrading metalloproteinases are composed mainly of the MMP (matrix metalloproteinase) and ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs) gene families.
- Most endogenous proteinase inhibitors are proteinase class specific, whereas α2 macroglobulin inhibits the activities of all proteinases.
- The activities of ECM-degrading proteinases at the local tissues are regulated by the balance between the proteinases and their inhibitors, which may be determined by production rates of proteinases and inhibitors, their secretion, activation of proenzymes, and pericellular anchoring and recycling systems of the activated proteinases.
- ProMMPs (precursors of MMPs) are activated via the extra-cellular, intra-cellular, and pericellular pathways depending on the MMP species.
- Aggrecan and type II collagen, two major ECM components, may be degraded in articular cartilage by differential or complementary actions of the MMP and ADAMTS species in arthritides.
- In rheumatoid arthritis, articular cartilage is destroyed by proteinases accumulated in synovial fluid, direct contact with proteolytic synovium and pannus tissue, and proteinases derived from chondrocytes, whereas bone is resorbed by osteoclasts mainly by the action of cathepsin K and MMP-9 under acidic and hypercalcemic conditions in subosteoclastic compartments.
- In osteoarthritis, chondrocyte-derived metalloproteinases, including the MMP and ADAMTS species, contribute primarily to the breakdown of articular cartilage.

Extra-cellular matrix (ECM) plays critical roles in normal development and function of the organism by interacting with cells and supporting tissue structures. The in vivo cellular functions regulated by cell-ECM interaction include proliferation, differentiation, apoptosis, and motility. The proteolytic turnover and remodeling of ECM are transient and highly controlled under physiologic conditions, and excessive degradation of ECM components by proteinases causes tissue destruction in many pathologic conditions. In rheumatoid arthritis and osteoarthritis, ECM-degrading proteinases are elevated without sufficient endogenous inhibitors, and they are believed to play central roles in the destruction of articular cartilage and bone on the basis of a local imbalance between proteinases and inhibitors. This chapter provides up-to-date information about the ECM-degrading proteinases and their inhibitors.

## EXTRA-CELLULAR MATRIX–DEGRADING PROTEINASES

ECM is degraded by endopeptidases (i.e., proteinases) that act internally on polypeptide chains; little evidence is present for the roles of exopeptidases that cleave one or a few amino acids from the N- or C-terminus. Proteinases comprise aspartic proteinases, cysteine proteinases, serine proteinases, and metalloproteinases, which are classified according to catalytic mechanism. Proteinases from each of the four classes are involved in the degradation of ECM macromolecules.

### Aspartic Proteinases

Most aspartic proteinases have two aspartic acid residues in their catalytic sites, where the nucleophile that attacks the scissile peptide bond is an activated water molecule. Mammalian aspartic proteinases include the digestive enzymes (pepsin and chymosin), the intra-cellular cathepsin D and cathepsin E, and rennin. Among the proteinases belonging to this group, cathepsin D is the major aspartic proteinase involved in ECM degradation (Table 8-1). It exhibits proteolytic activity against most substrates such as aggrecan and collagen telopeptides with optimal pH between pH 3.5 and 5. Because of the acidic optimal pH and intra-cellular localization within lysosomes, cathepsin D is probably responsible for intra-cellular degradation of phagocytosed

**TABLE 8-1** Proteinases That May Be Involved in Degradation of Extra-cellular Matrix

| Enzyme | Source | Inhibitor |
|---|---|---|
| **Aspartic Proteinases** | | |
| Cathepsin D | Lysosome | Pepstatin |
| **Cysteine Proteinases** | | |
| Cathepsin B | Lysosome | Cystatins |
| Cathepsin L | Lysosome | Cystatins |
| Cathepsin S | Lysosome | Cystatins |
| Cathepsin K | Lysosome | Cystatins |
| Calpain | Cytosol | Calpastatin |
| **Serine Proteinases** | | |
| Neutrophil elastase | Neutrophils | α1 PI |
| Cathepsin G | Neutrophils | α1 Antichymotrypsin |
| Proteinase 3 | Neutrophils | α1 PI, elafin |
| Plasmin | Plasma | Aprotinin |
| Plasma kallikrein | Plasma | Aprotinin |
| Tissue kallikrein | Glandular tissues | Aprotinin; kallistatin |
| tPA | Endothelial cells; chondrocytes | PAI-1; PAI-2 |
| uPA | Fibroblasts; chondrocytes | PAI-1; PAI-2; PN-1 |
| Tryptase | Mast cells | Trypstatin |
| Chymase | Mast cells | α1 PI |
| **Metalloproteinases*** | | |
| MMPs | Tissue cells; inflammatory cells | TIMP-1, 2, 3, and 4; RECK for MMP-2, 7, 9, and 14 |
| ADAMTSs | Tissue cells | TIMP-3 |
| ADAMs | Tissue cells; inflammatory cells | TIMP-3; RECK for ADAM10 |

*For details of ADAMs, ADAMTSs, and MMPs, see Tables 8-2, 8-3, and 8-4.

ADAMs, A disintegrin and metalloproteinases; ADAMTSs, a disintegrin and metalloproteinases with thrombospondin motifs; MMPs, matrix metalloproteinases; PAI, plasminogen activator inhibitor; PI, proteinase inhibitor, PN, proteinase nexin; RECK, reversion-inducing, cysteine-rich protein with Kazal motifs; TIMP, tissue inhibitor of metalloproteinases; tPA, tissue-type plasminogen activator; uPA, urokinase-type plasminogen activator.

ECM fragments that previously were degraded in the extra-cellular spaces. However, a study on cartilage explant cultures using the aspartic proteinase inhibitor suggests the possibility that cathepsin D secreted extra-cellularly contributes to the degradation of aggrecan in articular cartilage.[1]

## Cysteine Proteinases

Cysteine proteinases are endopeptidases in which the nucleophile of the catalytic site is the sulfhydryl group of a cysteine residue. The ECM-degrading cysteine proteinases include lysosomal cathepsins B, L, S, and K and the calpains (see Table 8-1). Cathepsins B and L digest the telopeptide regions of fibrillar types I and II collagen, the nonhelical regions of types IX and XI collagen, and aggrecan at acidic pH. Cathepsin S has a similar spectrum of substrates within a broad range of pH values. Cathepsin K, also called *cathepsin O, O2*, or *X*, is a collagenolytic cathepsin that efficiently cleaves type I collagen at the triple helical regions at pH values between 4.5 and 6.6.[2] The proteinase also degrades gelatin and osteonectin. On the basis of data that cathepsin K is highly expressed by human osteoclasts[3] and that inactivating mutations or deletion of the gene result in an osteopetrotic phenotype in humans and animals, cathepsin K is believed to play a key role in bone resorption in joint diseases (see later discussion). Because cathepsins B, L, S, and K are expressed in synovium or articular cartilage or both in rheumatoid arthritis and osteoarthritis, they may also be involved in the cartilage destruction through degradation of the ECM macromolecules.[4]

Calpains are $Ca^{2+}$-dependent, papain-like cysteine proteinases that are ubiquitously distributed among mammalian cells. The best-characterized members of the calpain superfamily are μ-calpain and m-calpain, which also are called *conventional* (μ-calpain) and *classic* (m-calpain) *calpains*.[5] Calpains are involved in various pathologic conditions such as muscle dystrophy by acting intra-cellularly. They are present in the extra-cellular spaces and in osteoarthritic synovial fluid, and they can degrade aggrecan.

## Serine Proteinases

Serine proteinases require the hydroxyl group of a serine residue acting as the nucleophile that attacks the peptide bond. Serine proteinases include the largest number of proteinases, classified to about 40 families. Most serine proteinases can degrade ECM macromolecules. The major ECM-degrading serine proteinases in joint tissues are subsequently described (see Table 8-1).

### Neutrophil Elastase and Cathepsin G

Neutrophil elastase and cathepsin G are serine proteinases that are synthesized as precursors in promyelocytes in bone marrow and subsequently stored in the azurophil granules of polymorphonuclear leukocytes as active enzymes. Mature leukocytes do not synthesize elastase, but they mobilize azurophil granules to the cell surface and release the proteinases in response to various stimuli. Monocytes have low levels of elastase but lose the enzyme during the differentiation into macrophages. Neutrophil elastase and cathepsin G are basic glycoproteins with isoelectric points larger than 9 (neutrophil elastase) and about 12 (cathepsin G). They can be readily trapped in cartilage matrix that has a negative charge.

Neutrophil elastase and cathepsin G cleave elastin; the telopeptide region of fibrillar collagen types I, II, and III; other collagen types IV, VI, VIII, IX, X, and XI; and other ECM components such as fibronectin, laminin, and aggrecan at neutral pH. These serine proteinases also can be involved indirectly in the breakdown of ECM by activating the zymogen of matrix metalloproteinases (proMMPs)[6] and by inactivating endogenous proteinase inhibitors such as α2 antiplasmin, α1 antichymotrypsin, and tissue inhibitors of metalloproteinases (TIMPs).

### Mast Cell Chymase and Tryptase

Chymase and tryptase are packaged in secretory granules together with histamine and other mediators in mast cells, which are infiltrated in rheumatoid synovium. Chymase is a chymotrypsin-like proteinase with a broad spectrum of activity against ECM components such as type VI collagen[7] and aggrecan. It also activates proMMPs such as proMMP-1, 3, and 9.[6] Although prochymase is activated intracellularly and stored in the granules, the activity in the granules is limited at low pH and becomes fully active when released extra-cellularly. Tryptase is a trypsin-like proteinase that degrades type VI collagen[7] and fibronectin; it also activates proMMP-3.[6]

### Plasmin and Plasminogen Activators

Plasminogen is synthesized in liver and secreted to plasma. It can bind to fibrin and to cells, and after activation by plasminogen activators, plasmin readily digests fibrin. Membrane-bound plasmin also degrades many ECM components including proteoglycan, fibronectin, type IV collagen, and laminin.[8] Other important functions of plasmin are to initiate the activation of proMMPs,[6] activate latent cell-associated transforming growth factor (TGF)-β1, and act as proenzyme convertase. Plasmin is generated through activation of plasminogen mainly by plasminogen activators, principally two serine proteinases, tissue-type plasminogen activator (tPA) and urokinase-type plasminogen activator (uPA).

The tPA is synthesized as a proenzyme of 70 kDa and is secreted into the circulating blood primarily by endothelial cells, fibroblasts, chondrocytes, and tumor cells.[8] In addition to being a major activator of plasminogen for fibrinolysis, tPA plays a key role in the clearance of fibrin from the circulation.

The uPA molecule was first purified from urine as a proenzyme of 54 kDa.[8] It is converted to the active form of two chains of 30 kDa and 24 kDa linked by a disulfide bond. Another fully active form of 33 kDa is generated by plasmin. Although the expression of uPA is limited to certain cells such as renal tubules and bladder urothelium under physiologic conditions, it is more widely expressed in various cells, including invasive cancer cells, migrating keratinocytes, and activated leukocytes in pathologic situations. Pro-uPA and two-chain uPA bind to a specific uPA receptor, a single-chain glycoprotein with a glycosylphosphatidylinositol (GPI) moiety expressed on fibroblasts, macrophages, and tumor cells. Receptor-bound uPA preferentially activates cell membrane–bound plasminogen into plasmin. Cell membrane–bound plasmin can activate receptor-bound pro-uPA. Among its specificities, uPA has a limited action on fibronectin.

### Kallikreins

Two types of kallikreins, plasma and tissue kallikreins, have been identified. Plasma kallikrein, with two disulfide-linked chains (36 kDa and 52 kDa), is generated from prokallikrein of 88 kDa by coagulation factor XIIa or by kallikrein itself. It activates kininogens to bradykinin and activates proMMP-1 and proMMP-3.[6] Tissue kallikrein, which is synthesized in glandular tissues, releases Lys-bradykinin from kininogen and activates proMMP-8.[6]

## Metalloproteinases

Similar to aspartic proteinases, metalloproteinases are endopeptidases in which the nucleophilic attack on a peptide bond is mediated by a water molecule. A divalent metal cation, usually zinc, activates the water molecule. Among the metalloproteinases, MMPs (matrix metalloproteinases), which are also designated matrixins (a subfamily of the metzincin superfamily), are key ECM-degrading, zinc-dependent endopeptidases (Table 8-2). However, accumulated evidence indicates that some members of the ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs) family, which is an MMP-related gene family, also are involved in the degradation of ECM, especially cartilage proteoglycan (Table 8-3). Only a few members of the ADAM (a disintegrin and metalloproteinase) family have limited activity to ECM components (Table 8-4).

### Matrix Metalloproteinases

The human MMP family comprises 23 different members that have MMP designations (numbered according to a sequential numbering system) and common names coined by the authors of the published reports (see Table 8-2). On the basis of the biochemical properties provided by the domain structures and on their substrate specificity, these family members are classified into two major subgroups: secreted-type MMPs and membrane-anchored MMPs. MMP-4, 5, and 6 are excluded from the list because they are identical to other known MMPs (i.e., MMP-3 and 2). MMP-18 and 22 also are missing in Table 8-2 because they are assigned to *Xenopus* collagenase-4 and chicken MMP.

Most secreted-type MMPs, including collagenases, stromelysins, are composed of three basic domains—the propeptide, catalytic, and hemopexin-like domains—that are preceded by hydrophobic signal peptides (Figure 8-1). The N-terminal propeptide domain has one unpaired cysteine in the conserved sequence of PRCGXPD. The cysteine residue in the sequence interacts with the essential zinc atom in the catalytic domain to prevent it from binding the catalytic water molecule, maintaining the proenzyme in an inactive state. The catalytic domain has the zinc-binding motif HEXGHXXGXXH, in which three histidines bind to the catalytic zinc atom. The four-blade, C-terminal hemopexin-like domain, which is connected to the catalytic domain by a proline-rich hinge region, interacts with ECM components and can play a role in determining the substrate specificity in some MMPs. Gelatinases have these domains with additional insertions of collagen-binding type II repeats of fibronectin in the catalytic domain (see Figure 8-1), which provides them with collagen-binding properties. Matrilysins are the shortest, lacking the hemopexin-like domains. Furin-activated MMPs contain insertions of a basic motif with a cleavage site by proprotein convertases including furin at the end of the propeptide domains (see Figure 8-1).

Membrane-anchored MMPs include three different types of MMPs: type I transmembrane-type MMPs, GPI-linked

**TABLE 8-2** Substrates of Human Matrix Metalloproteinases

| Enzymes | ECM Substrates | Non-ECM Substrates |
|---|---|---|
| **Secreted-Type MMPs** | | |
| **Collagenases** | | |
| MMP-1 (Interstitial collagenase) | Collagens I, II, III, VII, X; gelatins; aggrecan; link protein; entactin; tenascin; perlecan | α2 Macroglobulin; α1 PI; α1 antichymotrypsin; IGF-BP-2, -3, and -5; pro-IL-1β; CTGF |
| MMP-8 (Neutrophil collagenase) | Collagens I, II, and III; gelatins; aggrecan; link protein | α1 PI |
| MMP-13 (Collagenase-3) | Collagens I, II, III, IV, IX, X, XIV; aggrecan; Fn; tenascin | CTGF; pro-TGF-β; α1 antichymotrypsin |
| **Gelatinases** | | |
| MMP-2 (Gelatinase A) | Gelatins; collagens IV, V, VII, XI; Ln; Fn; elastin; aggrecan; link protein | Pro-TGF-β; FGF receptor I; MCP-3; IGF-BP-5; pro-IL-1β; galectin-3; plasminogen |
| MMP-9 (Gelatinase B) | Gelatins; collagens III, IV, V; aggrecan; elastin; entactin; link protein | Pro-TGF-β; IL-2 receptor α; Kit-L; IGF-BP-3; pro-IL-1β; α1 PI; galectin-3; ICAM-1; plasminogen |
| **Stromelysins** | | |
| MMP-3 (Stromelysin-1) | Aggrecan; decorin; gelatins; Fn; Ln; collagens III, IV, IX, X; tenascin; link protein; perlecan | IGF-BP-3; pro-IL-1β; HB-EGF; CTGF; E-cadherin; α1 antichymotrypsin; α1 PI; α2 macroglobulin; plasminogen; uPA; proMMP-1, 7, 8, 9, 13 |
| MMP-10 (Stromelysin-2) | Aggrecan; Fn; Ln; collagens III, IV, V; link protein | ProMMP-1, 8, 10 |
| **Matrilysins** | | |
| MMP-7 (Matrilysin-1) | Aggrecan; gelatins; Fn; Ln; elastin; entactin; collagen IV; tenascin; link protein | Pro-α-defensin; Fas-L; β4 integrin; E-cadherin; pro-TNF; CTGF; HB-EGF; RANKL; IGF-BP-3; plasminogen |
| MMP-26 (Matrilysin-2) | Gelatin; collagen IV; Fn; fibrinogen | α1 PI; proMMP-9 |
| **Furin-Activated MMPs** | | |
| MMP-11 (Stromelysin-3) | Fn; Ln; aggrecan; gelatins | α1 PI; α2 macroglobulin; IGF-BP-1 |
| MMP-28 (Epilysin) | Unknown | Casein |
| **Other Secreted-Type MMPs** | | |
| MMP-12 (Metalloelastase) | Elastin; Fn; collagen V; osteonectin | Plasminogen; apolipoprotein A |
| MMP-19 (RASI-1) | Collagen IV; gelatin; Fn; tenascin; aggrecan; COMP; Ln; nidogen | IGF-BP-3 |
| MMP-20 (Enamelysin) | Amelogenin; aggrecan; gelatin; COMP | Unknown |
| MMP-21 | Unknown | Unknown |
| MMP-27 | Unknown | Unknown |
| **Membrane-Anchored MMPs** | | |
| **Type I Transmembrane-Type MMPs** | | |
| MMP-14 (MT1-MMP) | Collagens I, II, III; gelatins; aggrecan; Fn; Ln; fibrin; Ln-5 | ProMMP-2, 13; CD44; tissue transglutaminase |
| MMP-15 (MT2-MMP) | Fn; tenascin; nidogen; aggrecan; perlecan; Ln | ProMMP-2; tissue transglutaminase |
| MMP-16 (MT3-MMP) | Collagen III; Fn; gelatin | ProMMP-2; tissue transglutaminase |
| MMP-24 (MT5-MMP) | PG | ProMMP-2 |
| **GPI-Linked MMPs** | | |
| MMP-17 (MT4-MMP) | Gelatin; fibrinogen | Unknown |
| MMP-25 (MT6-MMP) | Gelatin; collagen IV; fibrin; Fn; Ln | ProMMP-2 |
| **Type II Transmembrane-Type MMP** | | |
| MMP-23 | Gelatin | Unknown |

COMP, Cartilage oligomeric matrix protein; CTGF, connective tissue growth factor; ECM, extra-cellular matrix; FGF, fibroblast growth factor; Fn, fibronectin; GPI, glycosylphosphatidylinositol; HB-EGF, heparin-binding epidermal growth factor; IGF-BP, insulin-like growth factor binding protein; ICAM-1, intercellular adhesion molecule 1; IL, interleukin; Ln, laminin; MCP, monocyte chemoattractant protein; MMP, matrix metalloproteinase; PG, proteoglycan; PI, proteinase inhibitor; RANKL, receptor activator for nuclear factor-κB ligand; TGF, transforming growth factor; TNF, tumor necrosis factor; uPA, urokinase-type plasminogen activator.

MMPs, and type II transmembrane-type MMPs. MMP-14, MMP-15, MMP-16, and MMP-24 (MT1-, MT2-, MT3-, and MT5-MMPs, respectively) have type I transmembrane domains in the C-terminal region, but MMP-17 (MT4-MMP) and MMP-25 (MT6-MMP) contain GPI anchors in the C-terminal region without transmembrane domains (see Figure 8-1). MMP-23 is unique in that it has type II transmembrane domain, a cysteine array, and an immunoglobulin-like domain instead of a hemopexin-like domain (see Figure 8-1).

## Secreted-Type Matrix Metalloproteinases

**Collagenases (MMP-1, MMP-8, and MMP-13).** The collagenases include MMP-1 (interstitial collagenase, collagenase-1), MMP-8 (neutrophil collagenase, collagenase-2), and

**TABLE 8-3** Members of the ADAMTS Family

| ADAMTS | Other Names | Demonstration of Proteinase Activity | Functions and Biochemical Features | Tissue and Cell Expression |
|---|---|---|---|---|
| ADAMTS1 | C3-C5; METH1; KIAA1346 | + | Digestion of aggrecan and versican; binding to heparin | Kidney; heart; cartilage |
| ADAMTS2 | Procollagen N-proteinase; hPCPNI; PCINP | + | Processing of collagen I and II N-propeptides | Skin; tendon |
| ADAMTS3 | KIAA0366 | + | Processing of collagen N-propeptides | Brain |
| ADAMTS4 | KIAA0688; aggrecanase-1; ADMP-1 | + | Digestion of aggrecan, brevican, and versican | Brain; heart; cartilage |
| ADAMTS5 | ADAMTS11; aggrecanase-2; ADMP-2 | + | Digestion of aggrecan | Uterus; placenta; cartilage |
| ADAMTS6 | — | – | — | Placenta |
| ADAMTS7 | — | – | — | Various tissues |
| ADAMTS8 | METH-2 | + | Digestion of aggrecan; inhibition of angiogenesis | Lung; heart |
| ADAMTS9 | KIAA1312 | + | Digestion of aggrecan | Cartilage |
| ADAMTS10 | — | – | — | — |
| ADAMTS12 | — | – | — | Lung (fetus) |
| ADAMTS13 | VWFCP; C9orf8 | + | Cleavage of von Willebrand factor | Liver; prostate; brain |
| ADAMTS14 | — | + | Processing of collagen N-propeptides | Brain; uterus |
| ADAMTS15 | — | + | Digestion of aggrecan | Liver (fetus); kidney (fetus) |
| ADAMTS16 | — | + | Digestion of aggrecan | Prostate; brain; uterus |
| ADAMTS17 | FLJ32769; LOC123271 | – | — | Prostate; brain; liver |
| ADAMTS18 | ADAMTS21; HGNC:16662 | + | Digestion of aggrecan | Prostate; brain |
| ADAMTS19 | — | – | — | Lung (fetus) |
| ADAMTS20 | — | + | Digestion of versican (and aggrecan) | Brain; testis |

*Proteinase activities are shown in 13 members of the ADAMTS family, but not in 6 other members.
ADAMTS, A disintegrin and metalloproteinases with thrombospondin motifs.

MMP-13 (collagenase-3). These MMPs attack triple helical regions of interstitial collagen types I, II, and III at a specific single site after the Gly residue of the partial sequences Gly-(Ile or Leu)-(Ala or Leu), located about three-fourths of the distance from the N-terminus. This cleavage generates fragments approximately three-fourths and one-fourth of the size of the collagen molecules. A biochemical study has disclosed the molecular mechanism of the cleavage: MMP-1 unwinds the triple helical structure by interacting with the α2(I) chain of type I collagen and cleaves the three α chains in succession.[9] MMP-13 is unique in that it cleaves α chains of type II collagen at two sites of the $Gly^{906}$-$Leu^{907}$ $Gly^{909}$-$Gln^{910}$ bonds.[10] All of these collagenases degrade the interstitial collagens, but their specific activities against the collagens are different; MMP-1, 8, and 13 preferentially digest types III, I, and II collagen.[10,11] Although rodents such as mice were originally thought to have only two collagenases (*MMP-8* and *MMP-13*) and to lack the *MMP-1* gene, rodent homologues of the human *MMP-1* gene were cloned and named mouse collagenase A and B (*Mcol-A* and *Mcol-B*).[12]

In addition to the interstitial fibrillar collagens, MMP-1, 8, and 13 degrade many other ECM macromolecules. MMP-1 digests entactin, collagen X, gelatins, perlecan, aggrecan, and cartilage link protein (see Table 8-2). MMP-8 digests aggrecan, gelatins, and cartilage link protein (see Table 8-2). MMP-13 hydrolyzes aggrecan; types IV, IX, X, and XIV collagens; fibronectin; and tenascin. Non-ECM substrates of MMP-1, 8, and 13 include α2 macroglobulin, α1 anti-proteinase inhibitor, α1 antichymotrypsin, insulin-like growth factor binding protein (IGF-BP)-2 and IGF-BP-3, connective tissue growth factor (CTGF), and pro-TGF-β (see Table 8-2).

**Gelatinases (MMP-2 and MMP-9).** MMP-2 (gelatinase A) and MMP-9 (gelatinase B) belong to the gelatinase subgroup. Both MMPs readily digest gelatins and cleave types IV and V collagen.[13,14] Elastin, aggrecan, and cartilage link protein also are substrates of the gelatinases. Although MMP-2 and 9 share such substrates, they have different activities on several ECM macromolecules. MMP-2, but not MMP-9, digests fibronectin and laminin,[13] and type III collagen and α2 chains of type I collagen are degraded only by MMP-9.[14] The gelatinases also process directly TGF-β into an active ligand (see Table 8-2). MMP-2 and 9 cleave fibroblast growth factor receptor type I and interleukin (IL)-2 receptor type α (see Table 8-2). MMP-9 also releases soluble Kit-ligand.[15] MMP-2 processes monocyte chemoattractant protein (MCP)-3 into an MCP-3 fragment deleting the N-terminal four amino acids, which can bind to CC-chemokine receptors and act as a general chemokine antagonist.[16]

**Stromelysins (MMP-3 and MMP-10).** The subgroup of stromelysins consists of MMP-3 (stromelysin-1) and MMP-10 (stromelysin-2). They share 78% identity in

**TABLE 8-4** Members of the Human ADAM Family

| ADAM | Other Names | Proteinase-Type (P) or Non–Proteinase-Type (NP) | Functions and Biochemical Features | Tissue and Cell Expression |
|---|---|---|---|---|
| ADAM2 | PH-30β; Fertilin-β | NP | Sperm/egg binding/fusion; binding to integrin α$\beta$1, α6β, and α9β | Sperm |
| ADAM7 | EAP I; GP-83 | NP | Binding to integrin α4β1, α4β7, and α9β1 | Testis |
| ADAM8 | MS2 (CD156) | P | Neutrophil infiltration; shedding of CD23 | Macrophages; neutrophils |
| ADAM9 | MDC9; MCMP; Meltrin-γ | P | Shedding of HB-EGF, TNF-p75 receptor, and APP; digestion of fibronectin and gelatin; binding to integrin α2β1, α6β1, α6β4, α9β1, and αVβ5 | Various tissues |
| ADAM10 | MDAM; Kuzbanian | P | Shedding of TNF, Delta, Delta-like 1, Jagged, N-cadherin, E-cadherin, VE-cadherin, Ephrin A2, Ephrin A5, Fas-l, IL-6R, APP, L1,CD44, and HB-EGF; digestion of collagen IV, gelatin, and myelin basic protein; presence of RRKR sequence | Kidney; brain; chondrocytes |
| ADAM11 | MDC | NP | Tumor suppressor gene (?) | Brain |
| ADAM12 | Meltrin-α; MCMP; MLTN; MLTNA | P | Muscle formation; presence of RRKR sequence; binding to integrin α4β1 and α9β1; digestion of IGF-BP-3 and -5; shedding of HB-EGF and epiregulin; digestion of collagen IV, gelatin, and fibronectin | Osteoblasts; muscle cells; chondrocytes; placenta |
| ADAM15 | Metargidin; MDC15; AD56; CR II-7 | P | Expression in arteriosclerosis; binding to integrin αvβ3, α5β1, and α9β1; digestion of collagen IV and gelatin; shedding of CD23 | Smooth muscle cells; chondrocytes; endothelial cells; osteoclasts |
| ADAM17 | TACE; cSVP | P | Shedding of TNF, TGF-β, TNF-p75 receptor, RANKL, amphiregulin, epiregulin, HB-EGF, APP, L-selectin, and CD44; presence of RRKR sequence; binding to integrin α5β1 | Macrophages; various tissues; carcinoma tissue |
| ADAM18 | tMDC III | NP | — | Testis |
| ADAM19 | Meltrin-β; FKSG34 | P | Formation of neuron; shedding of neuregulin, and RANKL; binding to integrin α4β1 and α5β1 | Testis |
| ADAM20 | — | P | Formation of sperm | Testis |
| ADAM21 | — | P | — | Testis |
| ADAM22 | MDC2 | NP | — | Brain |
| ADAM23 | MDC3 | NP | Binding to integrin αvβ3 | Brain; heart |
| ADAM28 | e-MDC II; MDC-Lm; MDC-Ls | P | Digestion of VWF, IGF-BP-3, and CTGF; shedding of CD23; binding to integrin α4β1, α4β7, and α9β1 | Epididymis; lung; stomach; pancreas |
| ADAM29 | svph1 | NP | — | Testis |
| ADAM30 | svph4 | P | — | Testis |
| ADAM32 | AJ131563 | NP | — | Testis |
| ADAM33 | — | P | Mutation in bronchial asthma patients; shedding of APP and KL-1; digestion of insulin B chain; binding to integrin α4β1, α5β1, and α9β1 | Lung (fibroblasts, smooth muscle cells) |
| ADAMDEC1 | — | P | — | Lymphatic system; gastrointestinal system |

ADAM, A disintegrin and metalloproteinase; ADAMDEC1, ADAM-like decysin 1; APP, amyloid precursor protein; CTGF, connective tissue growth factor; HB-EGF, heparin-binding epidermal growth factor; IGF-BP, insulin-like growth factor binding protein; IL-6R, interleukin-6 receptor; KL-1, kit ligand-1; RANKL, receptor activator of nuclear factor-κB ligand; TGF, transforming growth factor; TNF, tumor necrosis factor; VWF, von Willebrand factor.

amino acid sequence and have similar enzymatic properties.[17] The enzymes hydrolyze numerous ECM macromolecules including aggrecan, fibronectin, laminin, and collagen IV (see Table 8-2).[18] Types III, IX, and X collagen and telopeptides of types I, II, and XI collagen also are digested by MMP-3.[19] In addition to the ECM components, MMP-3 is active on IGF-BP-3, IL-1β, heparin-binding epidermal growth factor (HB-EGF), CTGF, E-cadherin, α1 antichymotrypsin, and α1 proteinase inhibitor (see Table 8-2). MMP-3 also activates many proMMPs.[6] A similar activator function has been identified for MMP-10.[20]

**Matrilysins (MMP-7 and MMP-26).** Matrilysins include MMP-7 (matrilysin-1) and MMP-26 (matrilysin-2), which are the smallest of the MMPs, having only the propeptide and catalytic domains. The substrate specificity of MMP-7 is similar to that of stromelysins, digesting numerous ECM

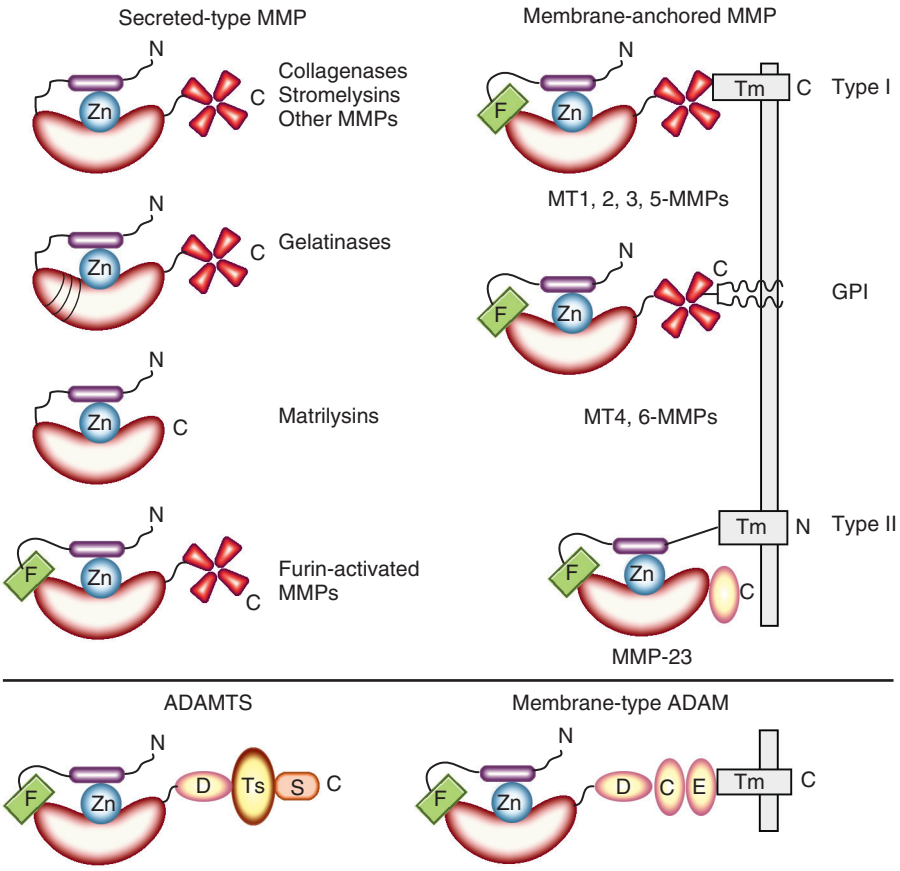

**Figure 8-1** Domain structures of two types of matrix metalloproteinases (MMPs) (secreted-type MMP and membrane-anchored MMP) and two types of a disintegrin and metalloproteinases (ADAMs) (a disintegrin and metalloproteinase with thrombospondin motifs [ADAMTS] and membrane-type ADAM). The typical domain structure of most secreted-type MMPs (collagenases, stromelysins, and other MMPs) is composed of a prodomain, catalytic domain, hinge, and hemopexin-like domain. Gelatinases (MMP-2 and MMP-9) have additional insertions of collagen-binding type II repeats of fibronectin in the catalytic domain, whereas matrilysins (MMP-7 and MMP-26) lack a hemopexin-like domain. Furin-activated MMPs (MMP-11 and MMP-28) contain an RKRR sequence (furin recognition site = F) at the end of the propeptide. Membrane-anchored MMPs are composed of type I transmembrane-type MMPs (MT1-, MT2-, MT3-, and MT5-MMPs); glycosylphosphatidylinositol (GPI)-linked MMPs (MT4- and MT6-MMPs); and type II transmembrane-type MMP (MMP-23). All of them have furin recognition sites. ADAMTS has a prodomain, a furin recognition site (F), a catalytic domain, a hinge, a disintegrin domain (D), thrombospondin motifs (Ts), and a spacer domain (S). Membrane-type ADAM is composed of a prodomain, furin recognition site (F), catalytic domain, hinge, disintegrin domain (D), cysteine-rich domain (C), EGF-like domain (E), and transmembrane domain (Tm). Zn, Active site zinc.

components, including aggrecan; gelatins; fibronectin; laminin; elastin; entactin; types III, IV, V, IX, X, and XI collagen; fibrin/fibrinogen; vitronectin; tenascin; and link protein (see Table 8-2). Although these substrates overlap with the substrates of other MMPs, the specific activity of MMP-7 to most substrates is highest among the MMPs.[21,22] Non-ECM molecules such as α-defensin, Fas ligand, β4 integrin, E-cadherin, plasminogen, tumor necrosis factor (TNF), and CTGF also are the substrates for MMP-7 (see Table 8-2). MMP-26 degrades gelatin, type IV collagen, fibronectin, fibrinogen, and α1 proteinase inhibitor,[23,24,25] but information about other substrates is still limited.

**Furin-Activated Matrix Metalloproteinases (MMP-11 and MMP-28).** MMP-11 (stromelysin-3) and MMP-28 (epilysin) contain an RKRR sequence at the end of the propeptide, which is a unique motif for intra_cellular processing of proproteins to mature molecules by furin and other proprotein convertases. ProMMP-11 is activated intra-cellularly by the action of furin.[26] MMP-11 shows only weak proteolytic activity against gelatin, laminin, fibronectin, and aggrecan,[27] but it has respectable catalytic action in digesting α1 proteinase inhibitor, α2 macroglobulin, and IGF-BP-1 (see Table 8-2).[28,29] MMP-28 can degrade casein, but its natural substrates are unknown.[30]

**Other Secreted-Type Matrix Metalloproteinases (MMP-12, MMP-19, MMP-20, MMP-21, and MMP-27).** MMP-12 (metalloelastase),[31] MMP-19 (RASI-1),[32] MMP-20 (enamelysin),[33] MMP-21,[25] and MMP-27 have structural characteristics similar to those of collagenases and stromelysins. These MMPs are not classified into the previously mentioned subgroups, however, because their substrates and other biochemical characters are not fully examined at present. Overall, information on the substrate specificity of MMP-12,[31] 19,[34,35] and 20[33,35] suggests that they are stromelysin-like proteinases. MMP-12[31] digests elastin, fibronectin, collagen V, osteonectin, and plasminogen (see Table 8-2). MMP-19, which was originally reported as MMP-18 but renamed as MMP-19, cleaves type IV collagen, laminin, fibronectin, gelatin, tenascin, entactin, fibrin/fibrinogen, aggrecan, and cartilage oligomeric matrix protein (COMP; see Table 8-2).[34,35] MMP-20 also digests amelogenin, aggrecan, and COMP.[35] Substrates of MMP-21 and 27 are unknown, however.

### Membrane-Anchored Matrix Metalloproteinases

Type I transmembrane-type MMPs include MMP-14 (MT1-MMP),[36] MMP-15 (MT2-MMP),[37] MMP-16 (MT3-MMP),[38] and MMP-24 (MT5-MMP).[39] All of these MT-MMPs can activate proMMP-2, but MMP-14 may play a major role in the activation of proMMP-2 in various tissues (see later discussion). Besides the activator function, however, MMP-14 digests the triple helical portions of interstitial collagen types I, II, and III and other ECM components, including fibronectin, laminin, aggrecan, and gelatin (see Table 8-2).[40] MMP-15 also digests fibronectin, tenascin, nidogen, aggrecan, perlecan, and laminin.[41] MMP-16 cleaves type III collagen, fibronectin, and gelatins.[42] MMP-17 (MT4-MMP)[43] and MMP-25 (MT6-MMP)[44] are GPI-linked MMPs. MMP-17 and MMP-25 can digest gelatin and fibrin/fibrinogen (see Table 8-2).[44–46] MMP-23 (cysteine array–MMP, MIFR) is a type II transmembrane-type MMP[47]; almost identical genes are cloned, called *MMP-23A* and *MMP-23B*. MMP-23 digests gelatin,[48] but no information about other substrates is available (see Table 8-2). A unique aspect of MMP-23 is that this MMP is expressed in only female and male reproductive organs such as endometrium, ovary, testis, and prostate,[48] but its functions are not well established.

### ADAM and ADAMTS Families

Two ADAM (a disintegrin and metalloproteinase) gene families exist: membrane-type ADAM with transmembrane domain (ADAM) and secreted-type ADAM with thrombospondin motifs (ADAMTS; see Figure 8-1). The active sites in the catalytic domains of most members of both gene families contain a common sequence of HEXGHXXGXXHD with the "Met-turn," which also is present in MMP members.

The ADAMTS family includes 19 members. Although information about substrates and biologic functions is still limited, ADAMTS1-5, 8-9, 14-16, 18, and 20 all are ECM-degrading proteinases (see Table 8-3). ADAMTS1,[49] 4,[50] 5,[51] 9, and 15 can preferentially cleave aggrecan at the five Glu-X bonds, including the $Glu^{373}$-$Ala^{374}$ bond (the aggrecanase site). Because of aggrecan-degrading activity, ADAMTS4 and ADAMTS5 are named aggrecanase-1 and aggrecanase-2[50,51]; versican also is digested by these proteinases,[52] and brevican is cleaved by ADAMTS4 (see Table 8-3).[53] The C-terminus–truncated ADAMTS4 also degrades fibromodulin and decorin.[54] ADAMTS16, 18, and 20 also appear to have weak aggrecanase activity. ADAMTS2 and 3 process the N-terminal propeptides of type I and II collagens and are named procollagen N-proteinase. Activity of procollagen N-proteinase also is known with ADAMTS14. ADAMTS13 is a von Willebrand factor–cleaving proteinase, and its mutation causes thrombotic thrombocytopenic purpura. Proteinase activities of other ADAMTS species are still unknown.

The human genome contains 25 *ADAM* genes, including 4 pseudogenes, and thus the human ADAM family is composed of 21 members (Table 8-4). Among the ADAMs, ADAM8-10, 12, 15, 17, 19-21, 28, 30, 33, and ADAM-like decysin 1 (ADAMDEC1) exhibit proteolytic activity (i.e., they are proteinase-type ADAMs; see Table 8-4). Although ADAM10, 12, and 15 degrade type IV collagen, the main substrates of these ADAMs are various membrane proteins, which include precursors of cytokines and growth factors such as TNF, HB-EGF and neuregulin, IGF-BPs, receptors such as p75 TNF receptor, IL-1 receptor II, and other membrane proteins related to development such as Notch ligand and ephrin (see Table 8-4).[55-60] According to these data, a major function of the ADAMs is shedding of the membrane proteins. ADAM17 cleaves a proform of TNF at the physiologic processing site into the soluble form of TNF and is called *TNF-converting enzyme*. ADAM17 also is involved in release of L-selectin, TGF-α, and p75 TNF receptor.[55] ADAM9, 12, and 17 can shed HB-EGF from its precursor. ADAM12 and 28 cleave IGF-BP-3 and IGF-BP-5.[60,61] CD23 is shed by ADAM8, 15, and 28.[62] Other functions of ADAMs include binding to integrins, cell-cell interaction, cell migration, and signal transduction (see Table 8-4).[63]

## ENDOGENOUS PROTEINASE INHIBITORS

Endogenous proteinase inhibitors control the activities of proteinases in vivo. The inhibitors are derived from plasma or cells in the local tissues. Plasma contains several proteinase inhibitors, and about 10% of all the plasma proteins are proteinase inhibitors. Most are proteinase class specific, but α2 macroglobulin inhibits the activities of proteinases from all four groups. Major endogenous inhibitors of the ECM-degrading proteinases are listed in Table 8-5.

### α2 Macroglobulin

The α2 macroglobulin molecule is a large plasma glycoprotein of 725 kDa that consists of four identical subunits of 185 kDa that are linked in pairs by disulfide bonds. The pairs assemble noncovalently. Almost all active proteinases, regardless of the proteinase classes, bind and attack the so-called bait region, located near the center of the subunit. After cleaving within the bait region, the proteinase is physically trapped within the molecule by inducing a conformational change of the inhibitor, resulting in a proteinase/α2 macroglobulin complex. Although the proteinase in the complex remains active against small substrates, it is trapped by the arms of the α2 macroglobulin from degrading larger proteins. Besides the function as a proteinase inhibitor, α2 macroglobulin may act as a carrier protein because it also binds to numerous growth factors and cytokines such as platelet-derived growth factor, basic fibroblast growth factor, TGF-β, insulin, and IL-1β.

The α2 macroglobulin molecule is synthesized mainly in liver but also locally by macrophages, fibroblasts, and adrenocortical cells. Concentration of the inhibitor in plasma is 250 mg/dL. Because of its large molecular weight, it is not present in non-inflammatory synovial fluid. During synovial inflammation, α2 macroglobulin penetrates into the joint cavity. Rheumatoid synovial fluid has about the same concentration of the inhibitor as plasma.

### Inhibitors of Serine Proteinases

The primary inhibitors of serine proteinases include the members of the serpin (serine proteinase inhibitor) gene family, Kunitz-type inhibitors, and others (see Table 8-5). The serpins are glycoproteins of 50 to 100 kDa and share

**TABLE 8-5** Endogenous Inhibitors of Extra-cellular Matrix–Degrading Proteinases

| Inhibitor | Molecular Mass (kDa) | Source | Target Enzyme |
|---|---|---|---|
| α2 Macroglobulin | 725 | Plasma (liver); macrophages; fibroblasts | Most proteinases from all classes |
| **Inhibitors of Serine Proteinase** | | | |
| **Serpins** | | | |
| α1 Proteinase inhibitor | 52 | Plasma; macrophages | Neutrophil elastase, cathepsin G, proteinase 3 |

ADAM, A disintegrin and metalloproteinase; EGF, epidermal growth factor; MMP, matrix metalloproteinase; NGF, nerve growth factor; PA, plasminogen activator; PAI, plasminogen activator inhibitor; RECK, reversion-inducing, cysteine-rich protein with Kazal motifs; SLPI, secretory leukocyte proteinase inhibitor; TIMP, tissue inhibitor of metalloproteinases; tPA, tissue-type plasminogen activator; uPA, urokinase-type plasminogen activator.

homology with human α1 proteinase inhibitor.[64] The major serpins involved in the regulation of ECM-degrading serine proteinases are α1 proteinase inhibitor, α1 antichymotrypsin, α2 antiplasmin, plasminogen activator inhibitors (PAI-1 and PAI-2), protein C inhibitor (PAI-3), C1-inhibitor, kallistatin, and proteinase nexin-1 (PN-1). The main proteinases inhibited by these molecules are listed in Table 8-5. Although PAI-1 and PAI-2 inhibit tPA and uPA, the inhibition by PAI-1 is more effective to tPA and that of PAI-2 is more efficient to uPA.

Kunitz-type inhibitors include aprotinin, trypstatin, and PN-2, which is identical to a β-amyloid protein precursor. Secretory leukocyte proteinase inhibitor, which inhibits neutrophil elastase and cathepsin G, is present in many secretory and inflammatory fluids and in cartilage. Elafin is a serine proteinase inhibitor with 38% identity with the second domain of secretory leukocyte proteinase inhibitor; it inhibits neutrophil elastase and proteinase 3.

## Inhibitors of Cysteine Proteinases

The members of the cystatin superfamily and calpastatin belong to the family of inhibitors of ECM-degrading cysteine proteinases (see Table 8-5). Cystatins that inhibit

lysosomal cysteine proteinases consist of three groups. Subgroup 1 comprises stefins A and B. Each has a molecular mass of 11 kDa, and the stefins reside within cells. Subgroup 2 comprises cystatin C and S, each with a molecular mass of 13 kDa. They occur at relatively high concentrations in cerebrospinal fluid and saliva. Subgroup 3 comprises the kininogens. Kininogens that participate in blood coagulation and inflammation also are inhibitors of cysteine proteinases. Calpains are not inhibited by cystatins but are inhibited by calpastatin (120 kDa), which is a cytosolic-specific inhibitor of calpain.

### Tissue Inhibitors of Metalloproteinases

TIMPs are a gene family consisting of four different members with approximately 40% to 50% sequence identity (i.e., *TIMP-1*, *TIMP-2*, *TIMP-3*, and *TIMP-4*) that have molecular masses ranging from 21 to 28 kDa in humans.[65-69] Virtually all TIMPs inhibit the activities of MMPs by binding in a 1:1 molar ratio to form tight, noncovalent complexes,[65] except that TIMP-1 does not efficiently inhibit MT-MMPs.[41,42,70] TIMPs contain 12 highly conserved cysteine residues that form six intrachain disulfide bonds, which are essential for maintaining the correct ternary structure of the molecule[67,71] and stable inhibitor activity.[65] The TIMP molecules have two structurally distinct subdomains: an N-terminal subdomain that consists of loops 1 through 3 and a C-terminal subdomain that consists of loops 4 through 6. The N-terminal subdomain of each TIMP molecule contains the inhibitory activity for MMPs.[65] Studies on the crystal structures of the MMP/TIMP complexes show that the wedge-shaped TIMPs bind with their edge into the entire length of the active-site cleft of their cognate MMPs.[67] High affinity and efficient inhibitor activity of TIMP-2 to MMP-14 (MT1-MMP) are explained by the interaction between a quite long hairpin loop of TIMP-2 and a loop over the rim of the active-site cleft of MMP-14.[72]

TIMP-1 and TIMP-2 are unique in that they make the complexes with proMMP-9 and proMMP-2 (i.e., the proMMP-9/TIMP-1 and proMMP-2/TIMP-2 complexes). Similar complex formation also is known between TIMP-4 and proMMP-2. Because the complexes are made through the interaction between their C-termini,[65] TIMPs in the complexes retain inhibitor activity against MMPs. The activation of proMMP-9 and proMMP-2 is suppressed in the complex forms; the complex formation may be a safety device for these gelatinases.[14] The proMMP-2/TIMP-2 complex is useful for the efficient activation of proMMP-2 by MMP-14 on the cell membranes because MMP-14 captures proMMP-2 to the cell membranes through the trimolecular complex formation between the catalytic domain of MMP-14 and the N-terminal domain of TIMP-2 (see later discussion).[73,74]

Besides the inhibition and interactions of TIMPs to MMPs, TIMP-3, among the TIMPs, most efficiently inhibits the activities of ADAM10, 12, 17, 28, and 33,[75] although ADAM8, 9, and 19 are not inhibited by TIMPs. Because TIMP-3 also efficiently inhibits the aggrecan-degrading activity of ADAMTS4 and 5, TIMP-3 may be a common tissue inhibitor of the ADAM members. The N-terminal subdomain of TIMP-3 is critical to the inhibition of the activities of ADAM members and MMPs, but the inhibition mechanism seems to be different.[76] TIMPs are multifunctional proteins with more diverse actions than MMP/ADAM inhibitors, including growth factor activity, antiangiogenic activity, and regulatory activity of apoptosis.[69]

Another new MMP inhibitor is *RECK* (*re*version-inducing, *c*ysteine-rich protein with *K*azal motifs).[77] RECK is a GPI-linked glycoprotein harboring three inhibitor-like domains and inhibits the activities of at least MMP-2, 7, 9, 14, and ADAM10. Although this inhibitor seems to play a key role in the angiogenic processes in vivo, its biochemical mechanism as an inhibitor to the MMPs and ADAM10 and its functions in pathologic conditions such as arthritides remain unknown.

## REGULATION OF PROTEINASE ACTIVITY

The activities of ECM-degrading proteinases in tissues are regulated by the balance between the proteinases and their inhibitors. The balance at the local tissues depends on several factors, including production rates of proteinases and inhibitors, their secretion, activation of proenzymes, and pericellular anchoring and recycling systems of the activated proteinases. Production levels of the proteinases and inhibitors within the cells are controlled mainly by their gene expression. Activation processes of proMMPs and membrane anchoring of their activities have been established by extensive experimental work.

### Gene Expression of Proteinases and Inhibitors

#### Matrix Metalloproteinases and Tissue Inhibitors of Metalloproteinases

Normal cells except for inflammatory cells produce only limited levels of MMPs or TIMPs in the tissues under physiologic conditions, but their expression is stimulated by many factors under pathologic conditions. Neutrophils and macrophages synthesize MMP-8 and MMP-9 during the differentiation and store them within the granules of the differentiated cells. Tumor cells express many MMPs such as MMP-1, 7, 9, 10, and MMP-14 (MT1-MMP), as well as TIMP-1, predominantly by oncogenic transformation. The gene expression of *MMPs* and *TIMPs* in the tissue cells other than inflammatory cells and tumor cells is regulated by numerous factors, however, including cytokines, growth factors, and chemical and physical stimuli.

Much information is available for regulators of *MMP-1* and *MMP-3*, which are coordinately expressed in many cell types after stimulation with cytokines and growth factors, factors acting at the cell surface, and chemical agents (Table 8-6). The induced production of MMP-1 and MMP-3 is suppressed by retinoic acid, TGF-β, and glucocorticoid. The gene expression of *MMP-7* and *MMP-9* is regulated by similar factors, but the regulation is stricter and fewer factors modulate the expression (see Table 8-6). *MMP-14* expression is upregulated by phorbormyristate acetate (12-*O*-tetradecanoylphorbol-13-acetate), concanavalin A, basic fibroblast growth factor, and TNF, and it is downregulated by glucocorticoids in various cells. TNF and IL-1α stimulate osteoarthritic chondrocytes to express the

*MMP-14* gene.[78] In contrast to these MMPs, MMP-2 and TIMP-2 are unique in that factors capable of enhancing the production of MMP-1, MMP-3, and TIMP-1 are inactive.

*TIMP-1* expression is enhanced or suppressed in response to many factors, including cytokines, growth factors, and oncogenic transformation (see Table 8-6). Effects of these stimulatory factors are common to the gene expression of *MMPs*, but they are regulated independently. TGF-β, retinoic acid, progesterone, and estrogen enhance *TIMP-1* expression in fibroblasts, but they suppress the expression of *MMP-1* and *3*. Although information about stimulating and suppressive factors of *TIMP-1*, *2*, and *3* is available (see Table 8-6), factors controlling the gene expression of *TIMP-4* are not well known. Previous studies have identified the elements in the promoters of *MMPs* and *TIMPs*, which are related to or responsible for the stimulation or suppression of the gene expression with various factors. Regulation of the gene expression is generally explained by the structural characteristics of the promoters.

## Serine Proteinases and Their Inhibitors

Neutrophil elastase, cathepsin G, chymase, and tryptase are stored within the secretory granules and secreted into the extra-cellular milieu after activation of neutrophils and mast cells. The expression of these serine proteinases is controlled mainly by the cellular differentiation. Precursors of plasmin and plasma kallikrein are constitutively synthesized predominantly in the liver, circulate in blood as zymogen forms (i.e., plasminogen and prekallikrein), and reach the inflamed tissues by being released from blood vessels. The proteinase activities in the tissues are controlled mainly through activation of the proenzymes by activators. The uPA and tPA molecules, activators of plasminogen, are synthesized by tissue cells, and their gene expression is regulated by many factors (Table 8-7). The uPA synthesis is upregulated in many normal cell types and in transformed cells by agents that increase intra-cellular cyclic adenosine monophosphate (cAMP) levels (e.g., calcitonin, vasopressin, cholera toxin, and cAMP analogues); growth factors (e.g., EGF, platelet-derived growth factor, and vascular endothelial growth factor); cytokines (IL-1 and TNF); and phorbol esters, whereas glucocorticoid decreases the expression.[8] The expression of *tPA* is regulated by similar factors (see Table 8-7). In endothelial cells, proteinases are enhancers; thrombin and plasmin stimulate the production of tPA.[8] *PAI-1* and *2* also are regulated by common factors, many of which also enhance the production of uPA and tPA (see

**TABLE 8-7** Factors That Regulate Expression of Plasminogen Activators and Their Inhibitors

| Enzyme or Inhibitor | Stimulatory Factor | Suppressive Factor |
|---|---|---|
| uPA | TPA; IL-1; IFN-γ; EGF; PDGF; bFGF; VEGF; TGF-β; cholera toxin; cAMP; estrogen; calcitonin; vasopressin; disruption of E-cadherin–dependent cell-cell adhesion | Glucocorticoids; TGF-β |
| tPA | TPA; EGF; bFGF; VEGF; retinoic acids; glucocorticoids; cAMP; thrombin; plasmin; follicle-stimulating hormone; luteinizing hormone; gonadotropin-releasing hormone | TNF |
| PAI-1 | IL-1; TNF; TGF-β; bFGF; VEGF; TPA; glucocorticoids | cAMP |
| PAI-2 | TPA; LPS; TNF; colony-stimulating factor; cholera toxin; dengue virus | Glucocorticoids |
| PN-1 | TPA; EGF; thrombin | Unknown |

bFGF, Fibroblast growth factor; cAMP, cyclic adenosine monophosphate; EGF, epidermal growth factor; IFN, interferon; IL, interleukin; LPS, lipopolysaccharide; PAI, plasminogen activator inhibitor; PDGF, platelet-derived growth factor; PN, proteinase nexin; TGF, transforming growth factor; TNF, tumor necrosis factor; TPA, 12-*O*-tetradecanoylphorbol-13-acetate; tPA, tissue-type plasminogen activator; uPA, urokinase-type plasminogen activator; VEGF, vascular endothelial growth factor.

Table 8-7). Most serpins are constitutively produced in the liver and secreted to plasma.

### Lysosomal Cysteine and Aspartic Proteinases

The expression of lysosomal cysteine proteinases, *cathepsins B, L,* and *K,* is generally constitutive, but cellular transformation is often associated with increased synthesis of cathepsins B and L. Cathepsin B transcription varies with cell type and the state of differentiation of tumor cells; it is increased in chondrocytes by IL-1. Malignant transformation, tumor promoters, and growth factors stimulate the synthesis of cathepsin L. *Cathepsin K* gene expression in monocyte-macrophage lineage depends on the cellular differentiation to osteoclasts, but all-*trans* retinoic acid upregulates the expression in rabbit osteoclasts. Lysosomal aspartic proteinase, *cathepsin D,* is constitutively expressed in almost all cells, although estradiol, calcitriol, and retinoic acid can regulate the expression.

## Activation Mechanisms of the Zymogens of Matrix Metalloproteinases

All of the MMPs are synthesized as inactive zymogens (proMMPs), and activation of proMMPs is prerequisite to their functioning in vivo. ProMMPs are kept inactive by an interaction between a cysteine-sulfhydryl group in the conserved propeptide sequence PRCGXPD and the zinc ion bound to the catalytic domain, preventing the formation of a water-zinc complex that is essential to the enzymatic reaction. Activation requires proteolytic removal of the propeptide domain. There are three pathways of proMMP activation—extra-cellular, intra-cellular, and pericellular (Figure 8-2).

### Extra-cellular Activation

Extra-cellular activation, which is applicable to many secreted MMPs (e.g., proMMP-1, 3, 7, 8-10, 12, and 13), is initiated through the disruption of the Cys-$Zn^{2+}$ interaction by treatment with nonproteolytic agents or proteinases and completed by autocatalytic processing.[6,69] Nonproteolytic activators used in vitro include thiol-modifying reagents (e.g., mercurial compounds, iodoacetamide, *N*-ethylmaleimide, and oxidized glutathione), hypochlorous acid, sodium dodecyl sulfate, chaotropic agents, and physical factors (heat and acid exposure).[6] Most of these factors, especially 4-aminophenylmercuric acetate (APMA), enable proMMP molecules to generate a short-lived intermediate, which is formed by removal of a part of propeptide by an intramolecular reaction.[6] The fully activated form is made by an intermolecular autocatalysis cleaving three amino acids downstream from the conserved sequence PRCGXPD and leading to generation of active MMPs, starting with Tyr or Phe at the N-terminus. Such a process may not be essential, however, for proMMP-9 activation by APMA because a fully active form retaining the PRCGVPD sequence is generated by the cleavage of the $Ala^{74}$-$Met^{75}$ bond upstream of the conserved sequence.[14] Concerning proMMP-9 activation during cerebral ischemia in vivo, nitric oxide is reported to activate proMMP-9 by *S*-nitrosylation.[79]

A similar stepwise activation is proposed for the proteolytic activation of proMMPs. Proteinases initially attack the proteinase-susceptible bait regions in the propeptides and generate proteolytically active intermediates through destabilization of the Cys-$Zn^{2+}$ interaction.[6] In the second step, the final activation site is autolytically catalyzed by the active intermediate instead of the trigger proteinases, and active MMPs without propeptides are made. In many cases, the bait region sequences in the propeptide dictate which proteinases can become an activator of a particular MMP.[6] Potential activators of proMMPs are listed in Table 8-8. Plasmin may play a major role in the activation of proMMP-3 and proMMP-10 in vivo because treatment of these proMMPs with plasmin leads to full activation in vitro.[80] ProMMP-1 activation by plasmin alone results in only about 25% of the potential MMP-1 activity, however, and full activation requires the subsequent cleavage of the $Gln^{80}$-$Phe^{81}$ bond by active MMP-3, 7, or 10.[6,22] MMP-3 and 10 can directly activate proMMP-7,[22] proMMP-8, proMMP-9,[14,20] and proMMP-13[11] into fully active forms. This intermolecular activation cascade of MMPs may be important to in vivo activation of proMMPs.

### Intra-cellular Activation

Because proMT-MMPs, proMMP-11, proMMP-23, and proMMP-28 have basic motifs containing an RXKR sequence at the end of the propeptide domains, proprotein convertases such as furin, a processing enzyme in the *trans*-Golgi apparatus, are considered to activate these proMMPs intra-cellularly (see Figure 8-2). Intra-cellular activation of

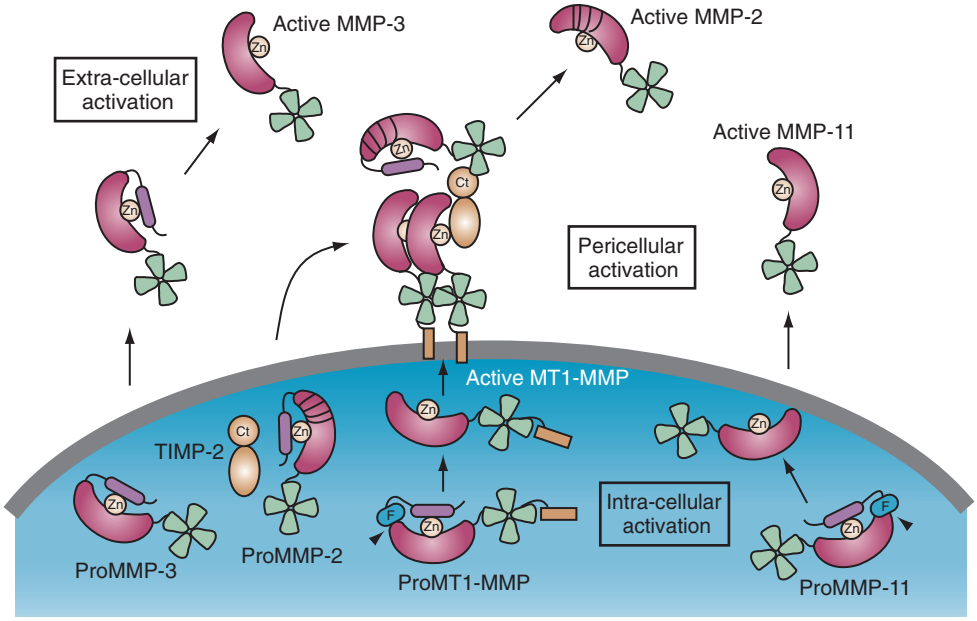

**Figure 8-2** Activation mechanisms of zymogen of matrix metalloproteinases (proMMPs). Most secreted-type proMMPs such as proMMP-3 are activated extra-cellularly by many proteinases (extra-cellular activation). Furin-activated secreted proMMPs, including proMMP-11, and proMT-MMPs, such as proMT1-MMP (proMMP-14), are intra-cellularly activated through removal of the propeptides *(arrowheads)* by the action of proprotein convertases such as furin (intra-cellular activation). ProMMP-2 is activated on the cell membrane by MT1-MMP (MMP-14); this activation requires the trimolecular complex of MT1-MMP/TIMP-2/proMMP-2 and dimerization of MT1-MMP (pericellular activation). Ct, C-terminal domain of TIMP-2; F, furin recognition site; TIMP, tissue inhibitor of metalloproteinase; Zn, active site zinc.

Pro-MMP, Pro-matrix metalloproteinase.

proMMP-11 and proMMP-14 (proMT1-MMP) by furin is shown.[26,81] After the activation, MMP-11 is secreted from the cells and MMP-14 is expressed on the cell membranes. Because other proMT-MMPs, proMMP-23, and proMMP-28 also have the motif, furin is presumably responsible for the intra-cellular activation of these proMMPs.

### Pericellular Activation

ProMMP-2 is unique in that it is activated pericellularly by MMP-14 (MT1-MMP), MMP-15 (MT2-MMP), MMP-16 (MT3-MMP), MMP-24 (MT5-MMP), and MMP-25 (MT6-MMP) but not by ordinary MMP-activatable endopeptidases.[13] MMP-17 (MT4-MMP) does not activate proMMP-2. This pericellular activation has been extensively studied with MMP-14 and found to occur in a two-step manner. MMP-14 cleaves the $Asn^{37}$-$Leu^{38}$ bond in the propeptide of proMMP-2, generating an intermediate form that is converted to a fully activated enzyme by an intermolecular autocatalytic mechanism.[70] TIMP-2 is essential to the efficient pericellular activation of proMMP-2 by MMP-14. The N-terminal inhibitor and C-terminal tail domains of TIMP-2 bind to the catalytic domain of MMP-14 and the C-terminal hemopexin-like domain of proMMP-2, forming a trimolecular complex of MMP-14/TIMP-2/proMMP-2 on the cell membranes (see Figure 8-2). Capturing proMMP-2 by the trimolecular complex formation on the cell membranes assists proMMP-2 activation by increasing a local concentration of proMMP-2 and presenting it to the near, noninhibited MMP-14.[73] Dimerization of MMP-14 through an interaction of the C-terminal hemopexin-like domain is required for the efficient activation of proMMP-2 by MMP-14.[82] MMP-14 initiates proMMP-2 activation by attacking a part of the proMMP-2 propeptide, and another already activated MMP-2 finally activates proMMP-2 by removing a residual portion of the propeptide. Integrins such as $\alpha v\beta 3$ may be involved in the process as an additional receptor for transferring activated MMP-2 to the integrin.[83] MMP-15, 16, or 24 can activate proMMP-2 in the transfected cells,[37-39,84]

but the activation mechanisms for these MT-MMPs are not well understood. MMP-14 also activates proMMP-13 on the cell surface,[85] and this activation does not seem to require TIMP-2.[86]

Pericellular activation of proMMP-7 has been discovered through screening proMMP-7–binding molecules by a yeast two-hybrid system.[87] ProMMP-7 is captured on the cell membrane by the interaction of the proMMP-7 propeptide with the C-terminal extra-cellular loop of CD151, a member of the transmembrane 4 superfamily, and is pericellularly activated.[87] This new pericellular activation of proMMP-7 requires a substrate of MMP-7. Since α chains of α3β1 and α6β4 integrins interact with CD151, these integrins also may be involved in the activation. Although the precise molecular mechanisms of this pericellular activation system, including the activator itself, are still unclear, proMMP-7 and CD151 are overexpressed in osteoarthritic chondrocytes, and proMMP-7 is activated by the interaction with CD151 in articular cartilage of osteoarthritis.[88]

### Pericellular Docking and Recycling of Matrix Metalloproteinases

Discovery of membrane-anchored MMPs (i.e., MT1-, MT2-, MT3-, MT4-, MT5-, and MT6-MMPs and MMP-23) and subsequent studies of proMMP-2 activation by MMP-14 (MT1-MMP) have established pericellular actions of these MMPs, including MMP-2. Secreted MMPs were originally thought to digest ECM macromolecules extra-cellularly after the activation, but more recent studies have indicated the possibility that they also may function on the cell membranes through their cell surface docking.[74,89,90] Besides the proMMP-2/TIMP-2/MMP-14 system, several secreted MMPs are reported to interact with cell membrane proteins, which include α2 chains of integrin α2β1 and CD147 (EMMPRIN) for MMP-1,[91] αvβ3 integrin and caveolin-1 for MMP-2,[83,92] CD44 heparan sulfate proteoglycan and cholesterol sulfate on the cell surface for MMP-7,[93,94] and CD44 for MMP-9.[95] Because all of these cell membrane proteins bind to active forms of the MMPs, their proteolytic activities can be used on the cell surfaces to digest ECM and non-ECM molecules located close to the cell membranes. On the other hand, MT1-MMP and secreted MMPs such as MMP-2 and 9 are internalized via clathrin-coated pits for recycling and low-density lipoprotein receptor–related protein-1 for catabolism in lysosomes, respectively. Pericellular docking and recycling indicate that pericellular activities of the MMPs are dynamically regulated. The importance of pericellular regulation of MT-MMPs and secreted MMPs by pericellular docking and clearing via internalization in arthritic tissues should be shown by further work.

## JOINT DESTRUCTION AND PROTEINASES

### Degradation of Extra-cellular Matrix in Articular Cartilage

In most joint diseases such as rheumatoid arthritis and osteoarthritis, articular cartilage is the major target tissue for destruction, and excessive degradation of cartilage ECM by proteinases is a key process in the destruction. Histologically, depletion of proteoglycans from articular cartilage (degradation of proteoglycans) is a common initial change in these joint diseases, and subsequently collagen fibrils are degraded, leading to fibrillation and laceration secondary to destruction of the arcade structures of collagen fibrils in the articular cartilage (Figure 8-3).

Aggrecan, a major proteoglycan in cartilage, is susceptible to degradation by many proteinases, including MMPs, ADAMTS species, neutrophil elastase, cathepsin G, and cathepsin B. Because most of these proteinases mainly cleave the peptide bonds located in the interglobular G1-G2 domain, the major glycosaminoglycan-bearing aggrecan fragments are detached from the hyaluronan attachment site (G1 domain) after the cleavage and released from the cartilage matrix. The two major aggrecan fragments with the N-terminal sequences starting from $Phe^{342}$ or $Ala^{374}$ of the core protein are detected in joint fluids from patients with various inflammatory arthritides and osteoarthritis.[96] Many MMPs, including MMP-1, 2, 3, 7, 8, 9, 13, and 14, preferentially cleave the $Asn^{341}$-$Phe^{342}$ bond (the MMP site).[21] ADAMTS species including ADAMTS1,[49] 4,[50] 5,[51] 8, 9, and 15 clip the $Glu^{373}$-$Ala^{374}$ bond (the aggrecanase site), in addition to other sites in the G2-G3 domains. Members of the MMP and ADAMTS families may play central roles in the aggrecan degradation in arthritides. On the basis of the data that synthetic MMP inhibitors do not efficiently prevent aggrecan degradation in articular cartilage, the focus has been on ADAMTS species as

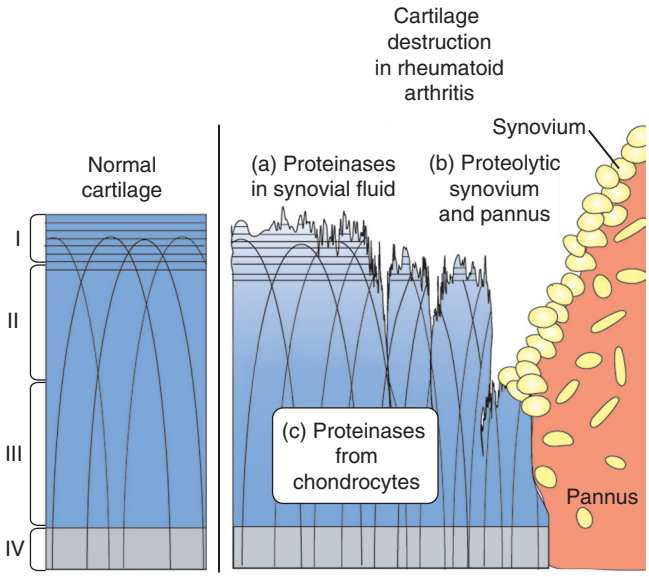

**Figure 8-3** Structure of normal articular cartilage and its destruction by proteinases in rheumatoid arthritis. Normal articular cartilage is divided into four zones (I, II, III, and IV). Collagen fibrils are aligned parallel to the articular surface in the superficial zone, and they blend with radial fibers and form plates or sheets that sweep vertically through the middle zone, showing arcade structures that originate from the calcified zone (IV). In persons with rheumatoid arthritis, synovial tissue cells and inflammatory cells produce various proteinases, most of which are secreted into synovial fluid. These proteinases in synovial fluid attack the surface of the articular cartilage from the synovial fluid *(a)*. At the periphery of the articular surface, proteolytic synovium degrades cartilage by direct contact, and pannus tissue covers and invades cartilage *(b)*. Chondrocytes, which secrete proteinases by stimulation with various cytokines and growth factors, also are implicated in cartilage destruction *(c)*.

aggrecan-degrading proteinases in arthritides. It is not settled, however, whether MMP and ADAMTS species play differential or complementary roles in the aggrecan degradation. Decorin, a leucine-rich repeat proteoglycan, also is digested by MMP-2, 3, and 7,[97] as well as ADAMTS4.[54] Information is limited about the proteinases responsible for the degradation of other proteoglycans, including fibromodulin, lumican, biglycan, PRELP (arginine-rich end leucine-rich repeat protein), chondroadherin, and syndecan present in articular cartilage, although fibromodulin is cleaved by C-terminus–truncated ADAMTS4.[54]

Fibrillar interstitial collagens (i.e., types I, II, and III collagens) are extremely resistant to most proteinases because of their triple-helical structures. In general, classic collagenases including MMP-1, 8, and 13 are responsible for the degradation of these collagens. Among them, MMP-13 may be most important for the degradation of cartilage collagen because it preferentially digests type II collagen.[11] MMP-14 degrades types I, II, and III collagens.[40] Type III collagen also is susceptible to degradation by MMP-3,[80] 9,[14] 16,[42] and neutrophil elastase. Cleavage of the telopeptides by the telopeptidase activity of MMP-3,[19] MMP-9,[14] neutrophil elastase, cathepsin G, and cysteine proteinase cathepsins is important for depolymerization of the cross-linked collagens. When the collagen molecules are cleaved, the helical structures are unwound at 37° C (i.e., body temperature) and become denatured into gelatins, which are digested into smaller peptides by gelatinases (MMP-2 and MMP-9)[13,14] and other nonspecific tissue proteinases. Type V collagen is readily digested by MMP-2[13] and MMP-9.[14] In contrast, type VI collagen is resistant to most MMPs, including MMP-1, 2, 3, 7, 9, 10, and 14, but is susceptible to neutrophil elastase, cathepsin G, chymase, and tryptase.[7] Type IX collagen is degraded by MMP-3.[19] Type X collagen is susceptible to MMP-1 and MMP-2, and type XI collagen is degraded by MMP-2.

Fibronectin is degraded by many MMPs, including MMP-2, 3, 7, 10, 11, 13-16, 19, and other serine proteinases. Link protein also is susceptible to many proteinases such as MMP-1, 2, 3, 7-10, neutrophil elastase, and cathepsin G. COMP is digested by MMP-19 and MMP-20.[35] Proteinases capable of digesting cartilage matrix protein and cartilage intermediate layer protein are unknown, however.

## Cartilage Destruction by Proteinases in Rheumatoid Arthritis

Articular cartilage in persons with rheumatoid arthritis is destroyed by proteinases in three pathways: (1) destruction from surfaces of articular cartilage by proteinases present in synovial fluid, (2) destruction through direct contact of proteolytic synovium or pannus tissue or both to articular cartilage, and (3) intrinsic destruction by proteinases derived from chondrocytes (see Figure 8-3).

Rheumatoid arthritis is characterized by chronic proliferative synovitis, which shows hyperplasia of the synovial lining cells, inflammatory cell infiltration, and angiogenesis in the sublining cell layer. Hyperplastic synovial lining cells overproduce MMP-1, 3, 9, 14, ADAMTS4, TIMP-1, and TIMP-3.[98-100] Sublining fibroblasts produce MMP-2 and TIMP-2. Polymorphonuclear leukocytes infiltrated in the synovium and joint cavity contain MMP-8 in the specific granules and MMP-9 and neutrophil elastase, cathepsin G, and proteinase 3 in the azurophil granules. They are released from cells during phagocytosis of tissue debris and immune complexes. Other inflammatory cells in the synovium include macrophages, lymphocytes, and mast cells. Macrophages produce MMP-1, MMP-9, TIMP-1, and TIMP-2, and uPA and cathepsins B, L, and D also are secreted from activated macrophages. T lymphocytes in the synovium synthesize MMP-9. Chymase and tryptase are degranulated from mast cells in response to activation by immune complexes. Endothelial cells express many MMPs, including MMP-1, 2, 3, 9, and 14; tPA; and their inhibitors. These proteinases may be involved in tissue remodeling during angiogenesis in the synovium instead of cartilage destruction.

All of these proteinases and inhibitors produced by synovial tissue cells and inflammatory cells seem to be secreted into the synovial fluid and attack the surfaces of articular cartilage when active proteinases overwhelm inhibitors. MMP-1, 2, 3, 8, 9, TIMP-1, and TIMP-2 are detectable in rheumatoid synovial fluids, and the molar ratios of MMPs to TIMPs correlate with metalloproteinase activity, which is detectable in rheumatoid synovial fluids.[101] MMPs are thought to be in favor of proteinase in rheumatoid synovial fluids. The cartilage in the central part of the articular surface shows surface irregularity (fibrillation) and proteoglycan depletion without being covered by pannus tissue even in the early stage of rheumatoid arthritis (Figure 8-4). This cartilage degradation may be ascribed to the proteolytic damage by the action of the proteinases present in synovial fluid (see Figure 8-3). Among the MMPs detected in synovial fluids, MMP-3 has the highest concentration and serum MMP-3 can be used to monitor the activity of rheumatoid synovitis.[102-104]

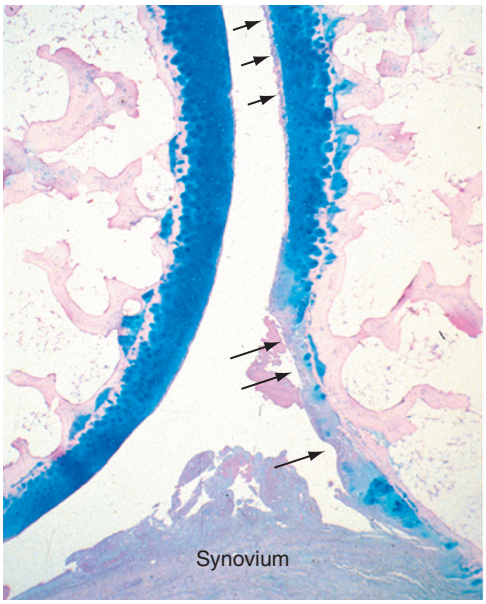

**Figure 8-4** Destruction of articular cartilage of the proximal interphalangeal joint obtained by autopsy from a patient with early-stage rheumatoid arthritis. Articular cartilage shows fibrillation and proteoglycan depletion at the central part of the articular surface *(short arrows)* and marked destruction at the marginal area, which contacts synovium *(long arrows)*. Alcian blue staining was performed for proteoglycans.

Articular cartilage at the margins of the articular surface, to which synovial tissue can directly attach, is progressively degraded even in the early stage (see Figure 8-4). Because rheumatoid synovial lining cells exhibit strong gelatinolytic activity, which is probably generated through activation of proMMP-2 by the action of MMP-14,[98] direct contact of the proteolytically active synovial tissue to articular cartilage is a destruction pathway of the cartilage (see Figure 8-3). Although rheumatoid synovium contains high concentrations of active proteinases, the synovium can avoid the attack by MMPs because type VI collagen, a major component in the lining cell layer,[105] is resistant to the activities of MMP-1, 2, 3, and 14.[40,105] Pannus tissue is a connective tissue growing from the marginal transitional zone on the surface of the partially degraded articular cartilage. It is unknown whether pannus tissue formation is a sign of active destruction or repair of the articular cartilage, but the balance of data favors the former. Immunolocalization of MMP-1 and phagocytosis of collagen fibrils by pannus cells at sites of pannus-cartilage junction may suggest a role of the tissue in the cartilage destruction.

In addition to the extrinsic pathway for the cartilage damage, cartilage may be destroyed by proteinases derived from chondrocytes (see Figure 8-3). Chondrocytes under stimulation are capable of expressing various proteinases, including MMP-1, 2, 3, 7, 9, 13, 14, 16, ADAM9, 10, 17, ADAMTS4, and other classes of proteinases. In rheumatoid arthritic cartilage, MMP-1, 2, 3, 7, 9, 13, and14 are expressed in the chondrocytes located in the proteoglycan-depleted zone. When large areas of the cartilage surface are ulcerated after degradation of cartilage ECM, death of chondrocytes occurs, leading to further progressive cartilage destruction.

Based on the data that MMPs play a central role in degradation of ECM molecules in rheumatoid arthritis and cancers, a number of MMP inhibitors were developed and used in clinical trials.[106-109] However, all of them failed because of no major clinical benefit and/or adverse effects. MMP inhibitors for the treatment of patients with rheumatoid arthritis and osteoarthritis were withdrawn from the phase III trials, mainly because of a lack of efficacy.[107] In clinical trials for patients with cancer, most of the inhibitors had no definite benefit, and prolonged or high-dose treatment with broad-spectrum MMP inhibitors caused unexpected symptoms in the musculoskeletal system, such as inflammatory polyarthritis,[110] which are called musculoskeletal syndrome.[111] The failure occurred mainly because the trials in the early stage were carried out with active site-directed broad-spectrum inhibitors, which cross-react with other MMPs and ADAMs/ADAMTSs. Thus one future strategy may be development of allosteric or exosite inhibitors that would exhibit higher specificity than conventional inhibitors targeting the active site.[109] However, another favorable type of inhibitor may be human antibodies to MMPs and/or ADAMTS4/5, which would be highly specific to the target proteinase.

## Bone Resorption in Rheumatoid Arthritis

Bone is resorbed by osteoclasts even in the early stage of rheumatoid arthritis. This phenomenon is commonly observed at the bare zone, where pannus-like granulation tissue invades the bone marrow and destroys subchondral bone. Activated osteoclasts attach to only mineralized bone matrix, and this cell-matrix contact is carried out between αvβ3 integrin of osteoclasts and Arg-Gly-Asp (RGD) sequence of osteopontin in the matrix. ECM degradation of the mineralized bone is possible only after demineralization of the bone matrix by proton secreted by osteoclasts because proteinases cannot permeate the matrix components in the mineralized tissues. Matrix degradation by osteoclasts is performed in the subosteoclastic compartments, which have acidic (pH 4 to 5) and hypercalcemic (40 to 50 mM $Ca^{2+}$) conditions.[112]

The major component of the ECM proteins in mature bone is insoluble, highly cross-linked type I collagen, although type III and V collagens also are present. Other minor components in bone matrix are leucine-rich repeat proteoglycans (decorin and biglycan) and glycoproteins such as osteopontin, osteonectin (SPARC), osteocalcin (bone Gla-protein), and thrombospondin. Among collagenolytic cysteine proteinases, including cathepsins B, K, L, and S, cathepsin K is the most important for bone resorption because of its collagenolytic activity with a broad pH optimum and selective expression in osteoclasts and giant cells of giant cell tumors. Mutations of human cathepsin K are responsible for pyknodysostosis, an autosomal recessive osteochondrodysplasia characterized by osteopetrosis and short stature.[113] *Cathepsin K*–deficient mice have a similar phenotype. Despite the importance of cathepsin K in bone resorption, osteoclastic bone resorption cannot be completely inhibited by cysteine proteinase inhibitors; it is inhibited to a similar degree by MMP inhibitors.[112] MMP-9 is highly expressed in osteoclasts in normal and rheumatoid bones[114] and giant cells of giant cell tumors. MMP-9 has telopeptidase activity against soluble and insoluble type I collagen and strong gelatinolytic activity.[14,114] ProMMP-9 is activated by acid exposure, and when activated, it is proteolytically active under acidic and hypercalcemic conditions.[114] *MMP-9*–deficient mice show a transient disturbance of growth plate development. Cathepsin K and MMP-9 may be involved in bone resorption in persons with rheumatoid arthritis. Although MMP-14 is reportedly expressed in osteoclasts in persons with rheumatoid arthritis,[115] evidence of the direct involvement in osteoclastic bone resorption is limited. MMP-7 may be involved in the solubilization of receptor activator of nuclear factor-κB ligand (RANKL) in a murine prostate cancer–induced osteolysis model,[116] but no data are available regarding the osteoclastic bone resorption in rheumatoid arthritis.

For treatment of osteoporosis and/or destructive bone diseases, bisphosphonates that reduce bone turnover by inhibiting bone-resorbing activity of mature osteoclasts are commonly utilized. Denosumab, a human monoclonal antibody against RANKL, has been approved by the U.S. Food and Drug Administration and used for treatment of osteoporosis in persons with rheumatoid arthritis. Phase II and III clinical trials of cathepsin K inhibitors are currently underway for treatment of post-menopausal osteoporosis. Because the reduction of osteoclast-stimulated bone formation is less compared with anti–bone resorptive drugs such as bisphosphonates,[117] these inhibitors might be useful for treatment of osteoporosis in persons with rheumatoid arthritis.

## Cartilage Destruction by Proteinases in Osteoarthritis

Prominent synovial inflammatory changes can be absent during early stages of osteoarthritis, but elevated production of enzymes by the chondrocytes themselves contributes to the breakdown of cartilage. Many MMPs, including MMP-1,[118] 2,[78,119] 3,[120] 7,[121] 8,[118] 9,[119] 13,[10,118] and 14,[78] are expressed in osteoarthritic cartilage. MMP-3, 7, and 14 are immunolocalized to chondrocytes in the proteoglycan-depleted zone of osteoarthritic cartilage, and the levels of their staining correlate directly with the histologic Mankin score.[78,120,121] Among the classic collagenolytic MMPs (i.e., MMP-1, 8, and 13), MMP-13 may be most important for degradation of the cartilage collagen because of preferential digestion of type II collagen over type I and III collagens.[10,11] Because MMP-14 efficiently activates proMMP-2 within the osteoarthritic cartilage,[78] and because it can activate proMMP-13,[86] MMP-14 may play a key role in cartilage degradation through activation of proMMP-2 and proMMP-13 and its own proteolytic activity against cartilage ECM. When considering intermolecular activation cascade for proMMPs by active MMPs, another key MMP in osteoarthritic cartilage tissue is MMP-3, which can activate proMMP-1, 7, 8, 9, and 13. MMP-3 not only digests many cartilage ECM components such as aggrecan, type IX collagen, and link protein but also activates those proMMPs. ProMMP-7 is activated pericellularly after being anchored via the complex formation with CD151 in osteoarthritic chondrocytes.[88] Because CD151 immunoreactivity directly correlates with the Mankin score and the degree of chondrocyte cloning and MMP-7 not only digests cartilage ECM but also sheds precursors of growth factors such as HB-EGF, MMP-7 may be involved in cartilage destruction, chondrocyte cloning, or both.[88]

Other proteinases implicated in cartilage destruction in osteoarthritis are members of the ADAMTS family. Chondrocytes are known to express ADAMTS1, 4, and 5, the latter two of which most efficiently degrade aggrecan. On the basis of the data that the cartilage destruction in experimental osteoarthritis is prevented in *ADAMTS5* knockout mice, but not in *ADAMTS4* knockout mice, ADAMTS5 is considered to play a key role in the cartilage destruction in mice.[122] In human osteoarthritic cartilage, however, ADAMTS4 is overexpressed, whereas ADAMTS5 expression is constitutive.[123] The expression of *ADAMTS4*, but not *ADAMTS5*, is stimulated with IL-1 and TNF in human osteoarthritic chondrocytes.[124] The differential role of ADAMTS4 and ADAMTS5 in human osteoarthritic cartilage remains elusive. Members of the ADAM family (i.e., *ADAM10*, *12*, *15*, and *17*) are expressed in osteoarthritic cartilage. ADAM12 may be involved in cartilage repair because ADAM12 is overexpressed by clustered chondrocytes and plays a role in chondrocyte proliferation by promoting the availability of IGF-I through cleavage of IGF-BP-5.[125] On the basis of data from *ADAM15* knockout mice, ADAM15 is considered to have a chondroprotective role in cartilage.[126] RECK is overexpressed by clustered chondrocytes in human osteoarthritic cartilage and may play a role in chondrocyte cloning (cluster formation) through suppression of chondrocyte migration and promotion of chondrocyte proliferation.[127]

PART 2 CELLS INVOLVED IN AUTOIMMUNE DISEASES AND INFLAMMATION

CHAPTER 9

# Dendritic Cells: General Overview and Role in Autoimmunity

Antoine Tanne • Nina Bhardwaj

## KEY POINTS

- Dendritic cells (DCs), together with monocytes and macrophages, comprise the mononuclear phagocyte system.
- DCs are professional antigen-presenting cells. They are abundant at body surfaces and within tissues, where they sense and sample the environment for self- and non–self-antigens.
- Three major subsets of DCs—plasmacytoid DCs, conventional DCs, and monocyte-derived DCs—are characterized by distinct origins, receptors, and functions.
- Upon antigen capture, DCs undergo a process of "maturation" exemplified by enhanced antigen processing, induction of major histocompatibility complex molecules, co-stimulatory molecules (CD80/86), and cytokine production. DCs migrate to primary and secondary lymphoid organs, where they present processed antigens to naïve T cells to induce immunity or tolerance.
- Mature DCs acquire the ability to differentiate naïve T cells into T helper (Th) 1, Th2, or Th17 cells, T follicular helper cells, or regulatory T cells. Maturing DCs also express cytokines that enable the activation of B cells and natural killer cells and promote the recruitment of other innate immune effector cells.
- DCs are innate immune phagocytic cells that sense the environment through membrane and cytosolic pattern recognition receptors. DCs contribute to the maintenance of tolerance in the thymus and in the periphery, although their functions are only partially understood.
- There is a fine equilibrium in DC regulation between tolerogenic and inflammatory states, which can contribute to autoimmune diseases or to tolerance of tumors.
- DCs, as one the main regulators of the immune response, can either be targeted or used as adjuvants to contain immunopathologies such as autoimmune diseases and cancers, respectively.

The first morphologic description of dendritic cells (DCs) was provided in 1973 by Drs. Ralph Steinmann and Zanvil Cohn.[1] Five years later, Dr. Steinmann proposed that DCs "will prove to be a critical accessory cell required in the generation of many immune responses."[2] Although not generally appreciated by the broader scientific community until many years later, DCs remain one of the most exciting discoveries in immunology in the 20th century. In 2011, jointly with Drs. Bruce Beutler and Jules Hofmann, who contributed to the discovery and the characterization of the role of Toll-like receptors (TLRs) in the regulation of innate immunity, Dr. Steinman received the Nobel Prize in Physiology or Medicine for the discovery of DCs and their role in the regulation of innate and adaptive immunology.

It is now well accepted that DCs are central players in immunity and in the maintenance of tolerance. DCs represent a sparsely distributed population of bone marrow–derived mononuclear cells that are found in most tissues of the body. They are professional antigen-presenting cells (APCs) that, in their immature state, have the ability to recognize and capture self- and non–self-antigens through expression of several pattern recognition receptors (PRRs).[3] DCs are activated upon encountering pathogen-associated molecular patterns (PAMPs) or danger-associated molecular patterns (DAMPs), which leads to a process of "maturation" that involves changes in the DC phenotype, antigen acquisition capacity, migration, and an ability to traffic to draining lymph nodes, where they prime cellular and humoral adaptive immune responses.[4] Upon maturation, DCs will process antigens (self and nonself) and then present them to antigen-specific adaptive immune cells (T cells and B cells) to induce immune responses to contain diseases such as cancer or infections, but also to maintain tolerance to self-antigens. Although most autoimmune cells are deleted in the thymus through a process of negative selection, others must be tolerized through active and sustained mechanisms.

This chapter summarizes our current understanding of the functions of DCs, their potential role in tolerance and autoimmunity, and their potential therapeutic use to contain immunopathologies. See Figure 9-1.

## DENDRITIC CELL SUBSETS

DCs have a broad tropism and have been identified in almost every tissue, including skin, intestine, heart, and primary and secondary lymphoid organs, as well as more recently in the brain parenchyma in mice.[5] All DCs share the key ability to present antigens to T cells; however, DC subsets differ considerably in ontogeny, tissue localization, cytokine profile, and immunologic functions.[6,7] Despite the identification and characterization of many different DC subsets in rodent and human tissue, the absence of specific

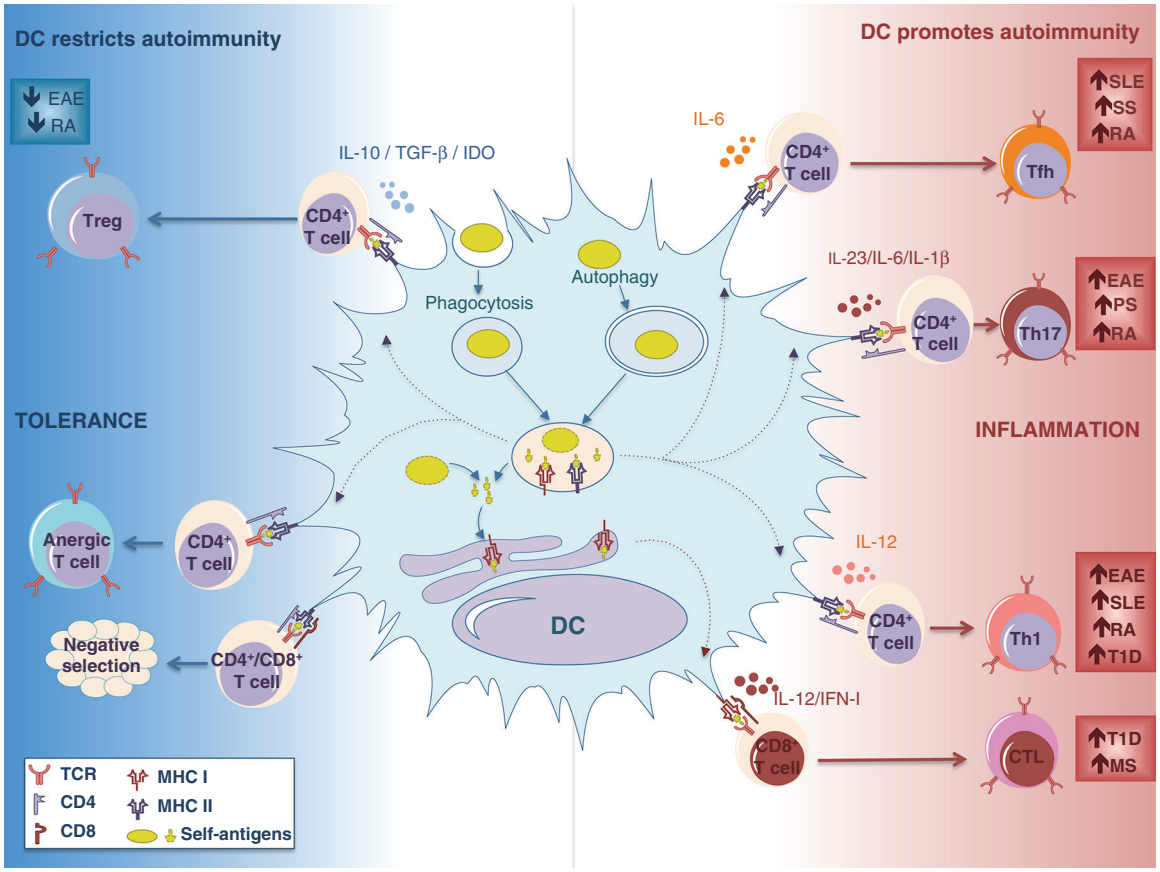

**Figure 9-1** Dendritic cells (DCs) play key roles in the regulation of tolerance and immunogenic response to autoantigens. DCs process autoantigens through phagocytosis and autophagy and present them on class I major histocompatibility complex (MHC I) or class II MHC (MHC II) molecules to CD4 T helper cells or CD8 cytotoxic T cells through processes including cross-presentation. DC-mediated presentation of self-antigen might promote or inhibit autoimmune responses, depending on the inflammatory context and the expression of cell-intrinsic immune regulators such as immune check points. The left part of the figure shows the presentation of self-antigens to T cells in the context of inhibitory factors, such as transforming growth factor–β (TGF-β), interleukin (IL)-10, or indoleamine-2,3-dioxygenase (IDO), which can promote their development into regulatory T (Treg) cells. Alternatively, DCs can induce T cell tolerance through anergy and can play a role in the negative selection of T cells in the thymus. In contrast, if DCs take up and present self-antigens to T cells in the context of pro-inflammatory mediators (such as IL-6, IL-12, IL-23, and interferon [IFN]-I), they can promote the development of an immunogenic response mediated by self-reactive effector $CD4^+$ T cells and cytotoxic T lymphocytes (CTLs). These self-reactive T cells can contribute to pathologic autoimmune responses, such as experimental autoimmune encephalomyelitis (EAE) in mice, multiple sclerosis (MS), Sjögren's syndrome (SS), systemic lupus erythematous (SLE), psoriasis (PS), rheumatoid arthritis (RA), and type 1 diabetes (T1D). IFN-I, Type I interferon; TCR, T cell receptor; Tfh, T follicular helper; Th, T helper. *(Modified from Ganguly D, Haak S, Sisirak V, Reizis B: The role of dendritic cells in autoimmunity.* Nat Rev Immunol *13:566–577, 2013.)*

DC precursors in bone marrow, as well as the absence of specific distinguishing phenotypic markers, has generated some skepticism about the relevance or existence of a DC lineage. However, recent studies infer the existence of such a lineage through the identification of specific transcription factors and cytokines that regulate DC development[8] and the isolation of DC progenitors that specifically give rise to DCs and no other immune cells.[6,7] Unlike B cells and T cells, which can be recognized by expression of surface immunoglobulin or T cell receptors (TCRs), respectively, DC subsets are heterogeneous based on their surface markers, although almost all DCs express class II major histocompatibility complex (MHC) antigens and different levels of the integrin αX (ITGAX), also known as CD11c.[6,7]

DCs are commonly divided into two main subsets: the conventional DCs (cDCs) and nonclassical DCs, which include plasmacytoid DCs (pDCs), monocyte-derived DCs (moDCs), and inflammatory monocyte–derived DCs (infDCs). This division of DCs into cDC, pDC, moDC, and infDC subsets likely presents an oversimplified view of DC heterogeneity. The heterogeneous nature of DCs presents a challenge for identifying developmental lineages; however, it is probably a reflection of the specialized functional role of DC subsets in different tissues and antigenic challenges, such as inflammation versus tolerogenic conditions.

## Conventional Dendritic Cells

Conventional DCs, or myeloid DCs, herein referred to as cDCs, comprise different subsets based on location, function, and phenotype. cDCs are APCs with high phagocytic activity as immature cells and high antigen presentation as mature cells, with the ability to secrete large quantities of cytokines. They have strongly evolved to constantly sense and respond to their environment and to appropriately interact with T cells. cDCs express myeloid markers (CD11c, CD33, and CD13) and high levels of class I MHC, class II MHC, and co-stimulatory molecules (CD80 and CD86).

cDCs are specialized in antigen processing; contrary to other phagocytes such as macrophages, which rapidly degrade antigens after their uptake, DCs process their cargo, allowing them to preserve and control the presentation of peptide epitopes on their MHC molecules. cDCs, in contrast to most other immune and nonimmune cells, can present endogenous and exogenous antigens in the context of both class I and II MHC. Presentation by class I MHC molecules primes $CD8^+$ T cells, whereas presentation by class II MHC molecules triggers $CD4^+$ T cells. Upon their phagocytosis, exogenous antigens are taken up into endosomal compartments, where proteases break down protein antigens into peptides for presentation on class II MHC molecules by DCs. Typically, antigenic peptides presented on class I MHC molecules are synthesized within the cytoplasm, where they are further processed before being shuttled to the endoplasmic reticulum to engage newly synthesized class I MHC molecules to then be exocytosed. The noncanonical presentation of exogenous noncytosolic antigens on class I MHC relies on vacuolar and cytosolic "cross-presentation pathways."[9] DCs can also present endogenous cytosolic antigens on class II MHC through autophagy, a process that allows for recycling of cytosolic compartment constituents through autophagosomes.[10]

cDCs are present in the circulatory system and can be found in virtually every peripheral tissue, as well as in lymphoid organs. To ensure the stimulation of naïve T cells, cDCs express chemokine receptors, such as CCR7. This expression allows directional migration toward T cell zones either within their respective lymphoid organs of residence or toward remote tissue-draining lymph nodes via afferent lymphatic and endothelial venules. Finally, cDCs are specialized in T cell cross-talk and are essential to activate naïve T cell and memory T cell responses, in addition to regulating follicular helper T cell (Tfh) responses, the latter being required for B cell differentiation. In lymph nodes, cDCs can regulate T cell responses both in steady state conditions (when they are typically not fully mature to induce tolerance or anergy) and during infection (after maturation, when they can prime a host T cell response). Depending on their maturation state and the profile of cytokines they secrete upon stimulation, they will prime naïve T cells toward various types of T helper (Th) cells, including Th1, Th2, Th17, Th22, Th9, and T regulatory (Treg) cells, which regulate specific aspects of the immune response to the antigen.[6,7,11,12]

cDCs can be subcategorized into three components according to their localization: (1) peripheral tissue resident, such as skin; (2) circulating blood cDCs; and (3) secondary lymphoid organ resident. Although many tissues have been studied in murine models, the skin remains the best described tissue in humans and will be our model to introduce the different DC subsets. Understanding of DC subsets is critical not only in any future development of vaccines or immunotherapeutic treatments, but also in the understanding of autoimmune disease pathogenesis, because each subset induces distinct responses.

## Tissue Resident cDCs

The skin is composed of two layers, the epidermis and the dermis, separated by a basal membrane. In healthy skin, three main DC subsets can be identified: The epidermis contains only Langerhans cells (LCs), whereas the dermis is highly vascularized and contains both tissue and circulating moDCs ($CD14^+$) and cDC subsets ($CD14^+$, $CD1a^+$, $CD1c^+$, and $CD141^+$). Upon skin infection or inflammation, nonconventional DCs (pDCs and infDCs) are locally recruited.

**Langerhans Cells.** LCs are self-renewing epidermal myeloid cells located in the epidermis, where they form a network between the keratinocytes. LCs are also observed in squamous stratified epithelia, such as the bronchus, and in oral and genital mucous membranes. They can migrate and mature into DCs. Compared to cDCs, LCs express shared common markers, such as CD11c, CD32, CD45, FcεR1, including CD1a and the C-type lectin receptor (CLR) langerin (CD207). Langerin delivers antigen through receptor-mediated endocytosis to Birbeck granules; these granules are structures connected to the endosomal network that are implicated in canonical and noncanonical antigen processing and presentation. In the steady state, similar to tissue resident macrophages, LCs are continuously replaced from a resident precursor pool, which is established early in development.[13] LC maintenance is dependent on factors produced by keratinocytes, including interleukin (IL)-34 in mice.[14,15] In inflammatory conditions, however, LCs appear to be repopulated by blood precursors.[12] LCs also present antigens in a CD1a-restricted manner.[16] The CD1 family of molecules is associated with presentation of glycolipids to specific subsets of T cells, such as the Dendritic epithelial T Cells (DETC) in the epidermis, which express γδ-TCR. CD1a antigen presentation is independent of endosomal localization and acidification.[17] LCs constitutively express E-cadherin (CD324), a homotypic adhesion molecule that anchors LCs to neighboring keratinocytes[12] and is released during LC maturation. Under steady-state conditions, immature LCs migrate to the lymph node and induce T cell tolerance.[18] In mice, LCs may induce the differentiation of Th1, Th2, Th17, and even Th22 cells.[19,20]

**Dermal Dendritic Cells.** In the steady state, dermal DCs are composed of $CD14^+$ DCs, a less characterized subset of $CD1a^+$ DCs, and two subsets of blood-derived circulating cDCs ($CD1c^+$ and $CD141^+$). Upon inflammation, infDCs and pDCs also accumulate locally.

**$CD14^+$ Dendritic Cells.** The $CD14^+$ dermal DCs were initially described as "interstitial/dermal type" DCs. They have an intermediate phenotype between DCs and monocytes/macrophages. They express macrophage and monocyte markers, such as CD163, CD11b (ITGAM), CXCR3CR1, and a broad spectrum of CLRs, including DEC-205 (CD205), LOX-1, CLEC6, DCIR (CLEC4a), DECTIN-1 (CLEC7a), and DC-SIGN (CD209).[21,22] $CD14^+$ dermal DCs have been shown to have a variety of functions, depending on the context in which they are evaluated. They can regulate B cell responses by differentiation of CD40-activated B cells into immunoglobulin (Ig) M–producing plasma cells through cytokine secretion (IL-12 and IL-6) and through direct cell-cell interaction.[23] $CD14^+$ DCs also promote antibody responses through skewing of $CD4^+$ T cells into Tfh cells, which induce naïve B cells to switch isotype and secrete large quantities of immunoglobulin.[24] $CD14^+$ DCs can skew $CD8^+$ T cells into TC2 cells in

a manner dependent upon the expression of Ig-like transcript inhibitory receptors ILT-2 and ILT-4. Finally, $CD14^+$ DCs, in the steady state, can induce Treg differentiation and promote tolerance.[25] Similar types of DCs can be generated in vitro from monocytes differentiated with IL-10 and vitamin D3, making it possible to better define the functions of this DC subset.[26]

**$CD1a^+$ Dermal DCs.** $CD1a^+$ dermal DCs express blood DC antigen-1 (BDCA-1 or CD1c), are present in the upper layer of the dermis, and can be found as $CD1a^+$ migratory DCs in the draining lymph nodes.[27] Phenotypically, they are similar to LCs but lack expression of langerin and E-cadherin. Upon stimulation, $CD1a^+$ DCs produce IL-15 and few pro-inflammatory cytokines.[28] They can induce Th2 responses and cytotoxic T lymphocyte (CTL) responses, although with less potency than LCs or $CD14^+$ DCs.[27]

## Circulating Dendritic Cells

Blood contains both cDCs and pDCs. cDCs can be found in healthy peripheral tissue, and when inflammation occurs, they are recruited into inflammatory sites, after which they migrate into secondary lymphoid tissue through afferent lymph. The physiologic roles of circulating blood cDCs include blood and tissue surveillance for pathogens and regulation of tolerance. cDCs in blood can be further subdivided into $CD1c^+$ ($BDCA\text{-}1^+$), $CD16^+$, and $BDCA\text{-}3^+$ populations, which differentiate from blood precursors. In addition, monocytes have been shown to differentiate into DCs, which can accumulate locally with pDCs in inflamed sites.

**$CD1c^+$/$BDCA\text{-}1^+$ Dendritic Cells.** $CD1c^+$ DCs originate from bone marrow, circulate in the blood, and migrate to peripheral tissues and secondary lymphoid organs (e.g., spleen and tonsil) as resting interstitial DCs.[6] They are characterized by the expression of CD1c, CD1a, CD11c, CD13, CD33, CD172 (SIRP1-α), CD45-RO and CD11b (ITGAM). They are sometime referred to the human double positive (hDP) DCs[3,8] and are hypothesized to be similar to mouse double positive (mDP) DCs expressing $CD11b^+$, CD172 ($SIRP1\text{-}\alpha^+$) but which are $CD8\alpha^+$.[8] $CD1c^+$ DCs possess a wide range of receptors such as TLRs and CLRs such as Dectin-1 (CLEC7A) and Dectin-2 (CLEC6A). IL-12p70 is efficiently produced by stimulated blood $CD1c^+$ DCs, whereas skin $CD1c^+$ DCs have a limited ability to produce IL-12 and CXCL10 (Interferon gamma-induced protein 10 [IP10]).[29] $CD1c^+$ DCs can promote Th1 or Th17 responses through IL-12p70 or IL-23 production. Similar to their murine counterparts, they have the capacity to present antigens to $CD4^+$ T cells but have limited ability to cross-present antigens to $CD8^+$ T cells. Whether they induce Treg differentiation and possibly regulate Th2 differentiation, as is done by their murine counterparts, has yet to be definitely established.[30]

**$CD141^{++}$/$BDCA\text{-}3^+$ Dendritic Cells.** CD141 expressing DCs are found in lymph nodes, tonsils, bone marrow, and spleen, where they localize to T cell areas. In the blood, they represent the minor subset of circulating cDCs. They do not express CD14 and have low levels of CD11c and CD11b. Sometimes referred to as human single-positive (hSP) DCs, they are considered to be the counterpart of mouse $CD11b^-$, $CD103^+$, $CD8\alpha^+$ DCs.[31,32] $CD141^{++}$ DCs express high levels of the chemokine receptor XCR1, TLR1, TLR2, TLR3, TLR7, and TLR8, as well as CLRs such as CLEC9A (DNRG-1) and BDCA-3 (CD141). They are characterized by production of IL-12p70 and IFN-β and have a superior capacity to induce Th1 cell responses when compared with $CD1c^+$ DCs. $CD141^{++}$ DCs can recognize and process dead or necrotic cells expressing β-actin via CLEC9A,[33,34] leading to cross-presentation of antigens to $CD8^+$ T cells. Because cross-presentation is essential for eradication of cancers, viruses, and other pathogens, $CD141^{++}$ DCs present a promising target in vaccination strategies. The selective expression of chemokine receptor XCR1 by $CD141^{++}$ DCs may promote their recruitment into sites of inflammation by activated natural killer (NK) cells and $CD8^+$ T cells, which produce XCL1, a ligand for XCR1.[35] Upon stimulation with TLR3 or -7/8 agonists $CD141^{++}$ DCs produce TNF, CXCL10 and high levels of anti-viral cytokine IFN-λ.

## Inflammatory Monocyte-Derived Dendritic Cells

Monocytes, which are precursors to macrophages, can differentiate into DCs (moDCs) in the presence of granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-4. They acquire DC morphology, produce inflammatory cytokines, and skew naïve T cell responses in vitro. TLR agonists such as lipopolysaccharide (LPS) or LPS-expressing bacteria can mediate differentiation of monocytes to moDCs.[36] Recently, inflammatory subsets of $CD11c^{++}$, class II $MHC^{++}$ moDCs have been described, including $CD14^+$ $CD1c^+$ human infDCs and inflammatory dendritic epidermal cells (IDEC); $CD14^-$ $CD1c^-$ TNF and INOS producing (TIP) DCs and 6-sulfo LacNAc–expressing (SLAN) DCs. However, those remain hard to segregate from SLAN monocytes, and their actual classification as DCs remains questionable. Immature SLAN DCs express FcγRII (CD16), which allows them to strongly interact with immune complexes (ICs). They tend to accumulate in skin lesions of cutaneous and systemic lupus erythematous (SLE) and in autoimmune diseases in which IC-containing autologous antigens SLAN DCs can contribute to the pathogenesis by stimulating disease activity.[37,38] All inflammatory DCs drive Th17 polarization by production of IL-6, IL-1β, TGF-β, and IL-23 to regulate Th17 skewing.[39]

## Plasmacytoid DCs

pDCs represent a subset of DCs that, in the steady state, resemble plasma cells and do not have dendrites. pDCs differ from cDCs in that they do not express CD11c but express CD4, CD123 (IL-3R), CD303 (CLEC4C/BDCA2), and the neuropilin CD304 (BDCA-4). pDCs are circulating DCs that can also be found in lymphoid tissues and rarely in healthy nonlymphoid tissue. In lymph nodes and tonsils, they accumulate in the T cell zone. When inflammation occurs, pDCs are rapidly recruited to tissue sites. pDCs have both pro-inflammatory and tolerogenic functions,[40] depending on their maturation status. They selectively express TLR7 and TLR9 that detect nucleic acids (single-stranded RNA [ssRNA] and single-stranded DNA [ssDNA]) derived from viruses, bacteria, and dead cells, or within

immune complexes in autoimmune conditions. TLR7 and TLR9 can trigger downstream signaling cascades, resulting in secretion of type I interferons (IFN-I) (IFN-α and IFN-β) and IFN-III (IFN-λ). In the steady state, pDCs have poor capacity to stimulate $CD4^+$ T cells because of their low level of expression of class II MHC. Upon activation, pDCs show similar characteristics to cDCs (e.g., dendritic structure and a high level of expression of class II MHC and co-stimulatory molecules) but remain less efficient at priming naïve T cells.[41] pDCs can prime naïve T cells toward the Th1 profile via production of IFN-α and IL-12 upon viral/TLR stimulation[42] but can also induce Tregs in an indoleamine-2,3,-dioxygenase (IDO)–dependent manner, possibly to contain immune activation, as in SLE or chronic human immunodeficiency virus (HIV) infection.[43] pDCs also seem to be able to cross-present antigens, particularly viral antigens.[44] In contrast to cDCs, pDCs contain "lymphoid" messenger (m)RNA transcripts for pre-T α chains, germline IgK, and Spi-B. pDCs have been shown to accumulate in inflamed tissues (as in early stages of psoriasis and SLE) through their expression of ChemR23 and CXCR4, and their failure to maintain tolerance to self–nucleic acid is linked to those autoimmune diseases.[45]

### Lymphoid Tissue–Associated Dendritic Cells

DC subsets are present in tonsils, lymph nodes, and spleen and comprise migratory cDCs, such as the $CD1c^+$ and $CD141^+$ subsets.[27] Certain specific DC subsets, such as intestinal DCs, can be found in the lamina propria, Peyer's patches, solitary lymphoid tissue, and mesenteric lymph nodes, where they process and sample luminal and self-antigens for presentation. $CD103^+$ DCs reside in intestinal lymph nodes and efficiently induce expression of gut homing receptors CCR9 and α4β7 by responding T cells and B cells through a retinoic acid receptor–dependent mechanism.[46] $CD103^+$ DCs can also induce the generation of Tregs from naïve $CD4^+$ T cells mediated through retinoic acid and TGF-β.[47,48] The function of secondary lymphoid tissue DC subsets in human autoimmune disease is still under investigation. In Crohn's disease, $CD103^+$ DCs maintain their ability to induce CCR9 expression by T cells, similar to healthy control DCs in small intestine,[49] although it remains to be determined whether they maintain their tolerogenic phenotype.

## DENDRITIC CELL DEVELOPMENT

DC development is complex, and although the ontogeny and functional specialization of different human DC subsets are beginning to be unraveled, the translation to human DCs remains complicated.

DC subsets develop from a distinct hematopoietic lineage from other members of the mononuclear phagocyte system (MPS). They are derived from the common DC progenitor (CDP).[50] Whereas the common monocyte progenitors (CMoPs) can generate monocytes, macrophages, and monocyte-derived DCs, the CDP has irreversibly lost the potential to generate monocytes and macrophages and can differentiate only into pDCs and cDCs.[51] Recent fate-mapping studies[52] and cellular bar-coding studies[53] have confirmed that cDCs represent an independent hematopoietic lineage. Once in the periphery, cDCs have a short life span but retain a high degree of plasticity, allowing the generation of multiple professional subsets that regulate either tolerogenic or immunogenic responses based on their final maturation and differentiation. Mutations in the *GATA2* gene generate a complete absence of multilymphoid progenitors (MLPs), which leads to the total absence of cDCs, monocytes, pDCs, and B and NK cells, whereas the granulocyte lineage is not affected.[54]

Human DC ontogeny is less well understood. *IRF8* gene mutations affect the myeloid lineage and lead to defects in cDCs, monocytes, granulocytes, and pDCs that resemble the phenotype induced by the hypomorphic mutation BXH-2 IRF8 in mice.[55,56] In this case, LC development is not affected in mice or human cells. These phenotypes suggest that similar to the mouse, the human cDC lineage develops from a myeloid and lymphoid common progenitor dependent on *GATA2* and then from an *IRF8*-regulated myeloid-dependent progenitor. The lack of DC subset–restricted markers complicates the identification of early human DC precursors in human blood. It has been proposed that human circulating cDCs ($CD1c^+$ and $CD141^+$) are not unipotent and can be considered forms of circulating precursors that can undergo final differentiation and specialization in situ.[6] In contrast, pDCs are unipotent when they leave the bone marrow, because both circulating and lymph node–derived pDCs do not proliferate.[6] Among the human MPS, DCs are distinguished from monocytes and macrophages by their structure, their high levels of class II MHC expression, their ability to migrate, and their ability to prime naïve T cells. The transcriptional profiling of the MPS components has confirmed that resting cDCs ($CD1c^+$ and $CD141^+$) and pDCs cluster together independently of monocytes and macrophages, which strongly suggests that the DC ontogeny model proposed in mice can be translated to humans.[57] On the other hand, moDCs and infDCs are associated with the monocyte lineage. Similarly to tissue macrophages, LCs seem to develop from an independent lineage related to embryonic tissue precursors. Considering lineage ontology, it is therefore questionable whether their classification as DCs is relevant or whether they should rather be classified as a specific type of tissue macrophage.

Recently Guilliams and collaborators[58] proposed a new system of nomenclature for the MPS. Three main developmental pathways have been proposed. The macrophage lineage is related to cells that develop from early embryonic precursors, such as tissue macrophages (e.g., alveolar and peritoneal), microglial cells, Kupffer cells, and LCs. Adult hematopoietic stem cells are then proposed to split into two lineages: the monocytic lineage derived from the cMoP, which give rise to monocytes and monocyte-derived cells, and the DC lineage, which derives from the CDP and differentiates into pre-cDC and pre-pDC. Pre-cDCs give rise to cDC1 dermal and lymphoid $CD141^+$ and to cDC2, which regroups the human lymphoid and dermal $CD1c^+$. Pre-pDCs give rise to pDCs.

### Dendritic Cell Maturation

DC maturation is one of the critical features of DC biology. This complex process relies on the acquisition of key

functional properties, such as environmental sensing, antigen uptake, processing and presentation, migration, and T cell stimulation.[59] The DC process of maturation is related to their environment and is therefore heterogeneous. It confers specific and distinctive functional properties to different DC subsets. It is important to consider DC maturation in the steady state versus upon inflammatory stimulation.

In the steady state, cDCs are in a quiescent state that is characterized by a low surface expression of MHC molecules and co-stimulatory molecules, such as CD80, CD86, and CD40. The program of maturation can be activated upon sterile and nonsterile inflammation and vaccination and to maintain homeostasis. DCs acquire the ability to induce clonal expansion and differentiation of antigen-specific naïve T cells into effector T cells. Immunogenic conditioning of cDCs induces class I MHC and class II MHC and T cell co-stimulatory molecule expression, such as CD80 and CD86. Additional changes include the regulation of endocytic properties, the induction of CCR7-dependent migration to follicular T cell–enriched zones in lymphoid organs, and the polarization of DCs toward a tolerogenic or immunogenic phenotype related to the profile of cytokines that they produce to induce the differentiation of naïve antigen-specific T cells, either Th1, Th2, Th17, Treg, or Tfh, or the activation of other immune cells.[3] Based on their environmental conditioning, DCs regulate the adaptation of T cell polarization to the specific nature of the stimuli. DC maturation relies on the sensing and sampling of the environment. The process requires the integration of multiple autocrine, exocrine, and paracrine signals through the recognition of cytokines, chemokines, growth factors (e.g., GM-CSF), and/or hormones, which can be produced by cells such as the MPS, lymphocytes, epithelial cells, and neurons. Although these stimuli may contribute to an autoimmune process, we will focus on recognition of DAMPs and PAMPs in the maturation of DCs as model stimuli.

## Phagocytosis and Autophagy

Phagocytosis is an active cellular process that allows MPS cells to sense, engulf, internalize, and process endogenous or exogenous antigens present in the extra-cellular environment. Autophagy is the process by which cells can process endogenously or exogenously derived intra-cellular components, including intra-cellular microbes (xenophagy) and organelles such as mitochondria (mitophagy). Autophagy and phagocytosis both contribute to maintaining homeostasis and to containing infection. Both phagosomes and autophagosomes will progressively acidify and terminate their maturation by fusing with lysosome to allow the degradation of their cargo. Depending on the cell type, the stringency of this process varies; the phagolysosomes of the DCs are less degrading than those of the macrophages or neutrophils.[60,61] Autophagy and phagocytosis contribute to inform myeloid cells about the nature of the targets that they are engulfing, including the nature of the cargo, whether it is dead or alive, and whether it is a threat. The integration of multiple signals allows the proper maturation of the MPS and DCs to regulate the local innate and adaptive immune response.

## Homeostatic Maturation

In the steady state, a fraction of cDCs undergo "homeostatic maturation."[62] They upregulate expression of class II MHC molecules at the cell surface and migrate to the lymphoid follicular T cell zones in a CCR7-dependent manner.[63] This homeostatic maturation program confers tolerogenic properties to cDCs.[64,65] As we will describe later, tolerogenic cDCs are thought to present self-antigen and to promote a tolerogenic environment to regulate peripheral tolerance to eradicate or inhibit self-reactive T cells that have escaped central tolerance. Thus steady-state cDC maturation is likely to play an important role in peripheral tolerance.

## Pattern-Recognition Receptors and Dendritic Cell Maturation

DCs sense their environment through a broad panel of PRRs. PRRs are highly conserved innate immune receptors that detect PAMPs or endogenous signals such as DAMPs. These PRRs are extremely diverse, detecting a wide range of molecular patterns, including proteins, lipids, carbohydrates, nucleic acids, and mineral crystals.[66] PRRs include the TLRs, the C-type lectins, the Nod-like receptors (NLRs), the retinoic acid–inducible gene (RIG)-I–like receptors (RLRs), the scavenger receptors (SRs), the integrins, and others such as the Ig Fc receptors (FcRs). These different receptor signal pathways can interact, and their integration allows a fine-tuning of the immune response adapted to specific conditions. Triggering of PRRs such as TLRs or C-type lectins on DCs is thought to be critical for their functional maturation and the priming of T cell responses to infection, therefore coupling innate and adaptive immunity.

**Dendritic Cell Maturation and Toll-like Receptors.** TLRs are highly conserved nonphagocytic PRRs that recognize many different specific molecular patterns, including PAMPs, such as microbial proteins, lipopeptides, glycopeptides, and nucleic acids, but they can also interact with some endogenous motifs such as nucleic acid.[67] In fact, inappropriate DC activation by these endogenous TLR agonists may contribute to autoimmune disease development, such as rheumatoid arthritis (RA), psoriasis, and SLE. Furthermore, in the steady state, TLR-mediated recognition of commensal microorganisms in the digestive tract contributes to tissue homeostasis via DC homeostatic maturation to maintain tolerance by retaining the integrity of the intestinal barrier. In fact, the knockout for certain TLR pathways in mice can increase susceptibility to the development of colitis.[26,68,69] TLRs can be grouped into two subfamilies based on their subcellular localization: the TLRs expressed on the cell surface (in humans and mice, TLR1, TLR2, TLR5, and TLR6, and restricted to mice, TLR11, TLR12, and TLR13) and those localized to specialized endosomal compartments (TLR3, TLR7, TLR8, and TLR9). Finally, TLR4 can localize to both sites.[70] Activation of DCs in response to binding of TLR agonists is controlled by signaling through the Toll/IL-1 receptor (TIR) domain present in the cytoplasmic domain of TLR. TLR ligands can induce DC maturation and regulate cellular processes, such as metabolism, life span,[71] cytoskeletal and organelle dynamics,[72] autophagy,[73] and intra-cellular sorting and processing

of endocytosed antigens.[74] Each DC subset expresses distinct panels of TLRs, which modulate their functional specialization. In response to infection or other abnormal conditions, pDCs are key producers of the type I IFNs. Human pDCs express high levels of nucleic acid–specific TLRs such as TLR7 and TLR9. TLR7 and TLR9 detect ssRNA and unmethylated cytosine-phosphatidyl-guanine (CpG) DNA, respectively, which are motifs usually found in both bacteria and viruses. TLR8 also recognizes bacterial ssRNA. Human $CD1c^+$ cDCs express mostly TLR1 through TLR8 and TLR10, whereas the $CD141^+$ cDCs express TLR1, TLR2, TLR3, TLR7, and TLR8.[75]

Overall, with regard to their TLR expression pattern, pDCs and $CD141^+$ cDCs appear to be more predisposed for the detection of intra-cellular pathogens, either directly or after phagocytosis and processing of material from infected cells, whereas $CD1c^+$ and moDCs might be more prone to detect extra-cellular pathogenic components. TLR stimulation by self- and non–self-antigens can regulate cytokines such as TNF, IL-12, IL-6, IL-23, and IL-17, which have an important role in the polarization of T helper cell subsets during priming by DCs, and thus the functional consequences of DC activation.

**C-Type Lectin Receptors.** C-Type lectins are another family of PRR that recognize sugar motifs in a calcium-dependent manner through their carbohydrate recognition functional domain. We will focus on the transmembrane CLRs, which are expressed at the surface of DCs and can recognize carbohydrate ligands of self, viral, bacterial, and fungal origins. The repertoire of CLR expression varies among the different DC subsets and is tightly regulated by the interactions with the environment. Some CLRs are almost restricted to specific DC subsets such as langerin on LCs. CLRs are involved in endocytosis, phagocytosis, antigen processing, and presentation through regular class II MHC or by class I MHC cross-presentation. Some of the CLRs regulate the immunomodulatory-transduction cascades through intra-cellular motifs such as the immunoreceptor tyrosine-based inhibitory motif (ITIM), which can induce the Src-homology phosphatase (SHP) cascade or the immunoreceptor tyrosine-based activation motif (ITAM), which signal through spleen tyrosine kinase (SYK) pathways.[76] Several CLRs, such as DEC205, mannose receptor (MR), and DC immunoreceptor (DCIR), have been shown to contribute to the cross-presentation of endocytosed antigens.

In most cases, CLRs fine-tune the immunogenic profile of DCs by regulating DC functions or modulating other pathways such as TLR signaling. It has been suggested that CLRs such as DEC205 contribute to immune tolerance in the absence of pro-inflammatory priming of DCs. However, various CLR-deficient mice show limited effects on tolerance induction and susceptibility to autoimmune diseases. In fact, only the genetic deletion of DCIR1, one of the murine homologues of DCIR (CLEC4A2), was associated with spontaneous induction of autoimmune disease (autoantibodies and RA-like syndromes) and immune homeostasis disruption.[77] DCIR1-deficient mice also have a higher susceptibility to collagen-induced arthritis. DCIR and DCIR1 contain ITIM domains, which are proposed to induce inhibitory pathways through SHP activation. Interestingly, SHP1 hypomorphic mutations in mice lead to autoimmune disease that is related to improper immune stimulation by commensal flora, probably mediated by either TLRs, CLRs, or other PRRs, which can be negatively regulated by SHP1 pathway induction.[78] Finally, activation of DCIR can negatively modulate TLR-induced inflammation.[79,80]

DC-specific intercellular adhesion molecule-3–grabbing nonintegrin (DC-SIGN or CD209) recognizes endogenous and exogenous mannosylated and fucosylated motifs. In humans, DC-SIGN contributes to the modulation of the immune response.[81,82] DC-SIGN can regulate the host pathogen interaction with the tick *Ixodes scapularis* by modulating TLR-dependent inflammatory cytokine production and reprofiling cytokines produced by the DCs in such a way that tolerance is induced and parasitism is favored. DC-SIGN also interacts with commensal bacteria such as lactobacilli.[83,84] DC-SIGN recognition of endogenous antigens has been associated with maintenance of tolerance in the central nervous system through recognition of fucosylated and glycosylated myelin.[85] Finally, in RA synovia, the numbers of cells expressing DC-SIGN on macrophages and DCs and intercellular adhesion molecule (ICAM)-3 on naïve T cells were increased in the affected joints, with interaction leading to increased secretion of matrix metalloproteinases, which promotes local tissue lysis and induces inflammation.[86]

BDCA-2 expressed by pDC pairs with FcεRγ, which contains an ITAM. Activation of BDCA-2 by antibody ligation has a tolerogenic effect and results in downregulation of TLR9-mediated response in pDCs.[87,88] Persons with SLE have reduced expression of BDCA-2 on pDCs, and the lack of negative regulation through BDCA-2 signaling may account for excessive IFN-α production upon TLR stimulation.[89] BDCA-2 and DEC-205 share similar immunomodulatory properties and have been targeted by recombinant antigens bound to antibodies in order to modulate DC function by inducing antigen-specific tolerance or immune stimulation with the addition of a maturation signal.[90]

Some other lectins can directly induce an immune response. Dectin-1 recognizes β-1,3 glucan expressed by fungal pathogens. Dectin-1 induces SYK-dependent signaling pathways that can regulate TLR cross-talk. Activation of Dectin-1 leads to the generation of Th1 and Th17 cells,[91] and it can participate in the induction of disease in the SKJ mouse model of inducible RA; however, the function of dectin-1 in human RA remains speculative.[92]

Finally, many CLRs recognize ligands expressed by apoptotic or necrotic cells and participate in the uptake of these dead cells by DCs, although most of the clearing process is mediated by neutrophils and macrophages. Clearance of apoptotic cells in a steady-state condition is a non-inflammatory process and prevents accumulation of self-antigens, thus preventing autoimmune disease. The CLR contribution to apoptotic cell removal must be highly redundant because their silencing in mice does not seem to significantly increase the risk of developing autoimmune syndromes. On the other hand, some CLRs are implicated in the recognition of necrotic dead cells and induce DC activation and immunogenic responses. DNRG1 (CLEC9a) is expressed on $CD141^+$ DC and recognizes F-actin, which is expressed at the surface of necrotic cells. This interaction

induces immunogenic responses and promotes the cross-presentation of processed necrotic antigens on class I MHC.[93,94] In the same way, macrophage-inducible C-type lectin (MINCLE), which is another CLR that recognizes necrotic cells, can induce inflammatory responses.[95]

Because CLRs are involved in immune homeostasis, their dysregulation might contribute to the predisposition to autoimmune disease. This supposition is supported by associations of single-nucleotide polymorphisms of CLR and key components of their signaling pathways with a number of autoimmune diseases, including CLEC16A with type 1 diabetes, multiple sclerosis, juvenile RA, and inflammatory bowel disease; DCIR with RA; and CARD9 with the spondyloarthropathies, ankylosing spondylitis, and inflammatory bowel disease.

**Nod-like and Retinoic Acid-Inducible Gene I–like Receptors.** NLRs and RLRs are cytoplasmic receptors that modulate nuclear factor-κB (NF-κB) or inflammasome signaling pathways through the recruitment and the activation of caspase reaction cascades.[96] The inflammasome is a complicated multiprotein complex that can be activated through PRRs by PAMPs or DAMPs and induces the activation of key inflammatory cytokines, such as IL-1β and IL-18, and regulates an inflammatory cell death pathway known as pyroptosis.[97]

RLRs recognize genomic or replication intermediate viral double-stranded RNA (dsRNA). The RLR family is composed of RIG-I, melanoma differenciation-associated protein 5 (MDA5), and the RIG-I like RNA helicase DHX-58 (LGP2). RIG-I and MDA5 directly activate a signaling cascade, leading to expression of type I IFN genes via TNF receptor–associated factor (TRAF)-3 and IFN response factor (IRF)-3/7. LGP2 is a modulatory co-receptor of RIG-I and MDA5 and can negatively modulate immune response to dsRNA. RLRs are key immunomodulatory PRRs in the regulation of anti-viral immunity, rather than in homeostasis, and may contribute to the development of inflammatory syndromes related to primary viral infections.[97]

NLR family proteins have a conserved structure but different functional domains. NOD1 and NOD2 sense various bacterial PAMPs in the cytoplasm and induce inflammatory cytokines through RIP-K2 (Receptor-interacting serine/threonine-protein kinase 2)-dependent of NF-κB and mitogen-associated protein kinases (MAPKs). NACHT-LRR-PYD–containing protein-3 (NALP3) and the NLR family apoptosis inhibitory protein-5 (NAIP5) regulate inflammasome activation through PRR and possibly RLR. IL-1β, IL-18, and IL-33 are the key inflammatory cytokines whose production is dependent initially on PRR-mediated transcriptional upregulation and translation of their proforms and subsequently into their active forms through activation of caspase-1 as a result of inflammasome activation.[97] Therefore the inflammasome is a key regulator of local inflammation, which can be activated directly or indirectly by various ligands. The NALP3 inflammasome can be induced by exogenous ligands such as viral RNA and by host endogenous ligands, including monosodium urate (MSU) and adenosine triphosphate (ATP). The inflammasome is associated with different autoinflammatory diseases, including RA.[98] Gout, an acute and chronic inflammation of joints, is associated with the deposition of MSU, which most likely induces inflammation through NALP3 inflammasomes.[99] NLRs have also been implicated in various inflammatory diseases, graft-versus-host syndrome, and autoimmune diseases. For example, the Muckle-Wells syndrome (MWS), familial cold autoinflammatory syndrome (FCAS), and neonatal-onset multisystem inflammatory disease (NOMID) have been shown to be associated with mutations in NLRP3, causing constitutive activation of the NLRP3 inflammasome.[98] Deletion of *ATG16L1*, an autophagy-related gene, leads to hyperactivation of inflammasomes and subsequent secretion of bioactive IL-1β and IL-18, which contribute to intestinal inflammation. *NOD2* regulates Th17 responses for clearance of bacteria through the selective induction of IL-23 and IL-1β, which is abrogated in DCs from persons with Crohn's disease who carry a mutation in *NOD2*.[100] Therefore inappropriate responses to exogenous stimuli, such as bacteria from the microflora, may prime DCs into an inflammatory state, which contributes to the development of autoinflammatory or autoimmune diseases.

**Fc Receptors.** FcRs, which are expressed by many immune cells, are important in regulation of immune responses to ICs composed of antigen bound to antibody and sometimes to components of the complement system. DCs express activating receptors FcγRI, FcγRIIA, FcγRIIIA, and inhibitory receptor FcγRIIB. Infected cells or pathogens coated with IgG activate FcγR-mediated clearance by antibody-dependent cell-mediated cytotoxicity (ADCC) or phagocytosis and/or indirectly through the release of cytokines. This process is mediated by ITAM phosphorylation and subsequent activation of SYK and the initiation of the downstream signaling cascade resulting in DC activation. In contrast, inhibitory FcγRIIB has an ITIM domain in its cytoplasmic tail, resulting in inhibition of phagocytosis and cytokine secretion. FcγRIIB also prevents spontaneous IC-mediated DC maturation by the low levels of ICs that can be identified in the serum of healthy persons.[101] In a small subset of patients with well-controlled RA who were able to stop taking disease-modifying drugs, peripheral blood monocyte-derived DCs expressed high levels of FcγRIIB, which inhibited TLR4-mediated DC activation.[102] In addition, ICs taken up by FcγRIIB are degraded inefficiently and are presented on the cell surface in native conformation, where they can negatively regulate B cell function to prevent autoreactivity.[103] An FcγRIIB gene polymorphism has been identified in persons with SLE and RA, and DCs from patients with RA who have an FcγRIIB variant manifested an increase in IC-mediated inflammation in vitro.[104]

FcγRs also alter CR3-mediated phagocytosis and signaling upon co-stimulation in vitro. CR3-mediated phagocytosis is inhibited upon co-stimulation of CR3 with FcγRI, whereas it is enhanced by FcγRIIA co-stimulation. Patients with SLE have been reported to have a high FcγRI and a low FcγRIIA expression, which can lead to inefficient CR3-mediated phagocytosis of apoptotic cell uptake, which affects homeostatic regulation.[105]

**Apoptotic Cell Recognition Receptors.** DCs also contribute to tissue homeostasis through clearance of apoptotic cells in the periphery by a process named *efferocytosis*. Contrary to necrotic or other inflammatory cell death, the uptake of apoptotic cells or apoptotic microparticles maintains DCs in an immature phenotype and induces

immunomodulatory effects.[106] These DCs downregulate co-stimulatory molecules (CD80/86) and produce TGF-β, a cytokine necessary for differentiation of naïve T cells to Tregs.[107] In a steady state, apoptotic cells are a source of self-antigen presentation by DCs and may contribute to tolerogenic DC homeostatic maturation and peripheral tolerance regulation.[108,109] Inefficient efferocytosis leads to the accumulation of apoptotic cells, which then evolve into secondary necrotic cells, which have been implicated in the development of SLE. Recognition and engulfment of apoptotic cells involve multiple ligands, including "eat me" signals, bridging molecules, and phagocytic receptors. One of the principal "eat me" signals is translocation of phosphatidylserine (PS) to the outer leaflet of the plasma membrane of apoptotic cells. Apoptotic cells and microparticles are recognized by a plethora of receptors that recognize molecular patterns enriched on apoptotic cells, such as certain sugars and phosphatidylserine. These receptors include integrins, scavenger receptors, milk fat globular-EGF factor-8 protein (MEGF-8), stabilin, low-density lipoprotein receptor, receptor tyrosine kinases, and proteins from the immunoglobulin family. The Tyro 3 subfamily of receptor tyrosine kinases—Tyro 3, Axl, and Mer (TAM)—bind through intermediate adaptor proteins to apoptotic cell membranes to trigger suppressors of cytokine synthesis (SOCS)-1 and SOCS-3 expression in DCs, which inhibit the TLR-induced and cytokine-induced signaling cascades and therefore immunogenic DC maturation.[110] Consistent with this view, TAM triple gene–deficient mice possess hyperactive DCs and develop systemic autoimmunity.[111] The uptake of apoptotic cells triggers TGF-β release, which leads to DC-mediated Treg induction. The DC-specific loss of TGF-β activation of integrin αvβ8 resulted in the failure of Treg development initiated by DCs in vitro and caused autoimmune colitis in mice.[48] The scavenger receptor SCARF1 regulates efferocytosis, and SCARF1-deficient mice recently have been associated with the development of SLE-like syndrome in mice, possibly because of the accumulation of apoptotic debris.[112] A common feature of patients with lupus is the presence of dying cells in both lymph nodes and inflamed tissues. It is not clear whether this phenomenon is due to increased cell death or innate or acquired inability to clear apoptotic cells, which normally occurs very rapidly. Increased cell death might be the consequence of oxidative stress or infection, both of which are thought to trigger autoimmune disease. Regardless of the mechanism, cell death accumulation increases the presence of autoantigens available for presentation by DCs. Apoptotic cells may eventually undergo secondary necrosis. Necrotic cells attract phagocytes by secreting hyaluronic acid, uric acid, and high-mobility group box-1 protein (HMGB1), which are known inducers of the inflammasome and can contribute to inflammatory priming and development of autoimmune disease.[113]

## Antigen Presentation

DCs are specialized in antigen processing and can efficiently present endogenous and exogenous antigens in both class I and II MHC contexts. As opposed to macrophages, cDCs degrade their engulfed cargo slowly and can control lysosomal degradation, potentially to preserve peptides for T cell recognition.[114] This activity is influenced by the maturation and activation status of the DC, which promotes phagolysosome maturation, peptide processing, peptide macropinocytosis, and DC metabolism to promote antigen processing and presentation of antigens by class I MHC and class II MHC, as well as lipid presentation by CD1 molecules.

### Class I Major Histocompatibility Complex Antigen Presentation

Class I MHC molecules are expressed in almost all cell types and present peptides derived from proteasome-digested cytosolic proteins, including endogenous, viral, or bacterial proteins, to $CD8^+$ T cells. Those antigenic peptides are predominantly generated from ubiquitinated nascent, misfolded, and neosynthesized defective proteins, defective ribosomal products (DRiPs), and cytoplasmic proteins. Peptides are transported to the endoplasmic reticulum (ER) through transporter associated with antigen processing (TAP) proteins, where long peptides are further trimmed to 8-mer or 9-mer peptides for loading onto class I MHC molecules. The trimeric complex of class I MHC heavy chains, β2-microglobulin, and peptide allows for optimal folding, glycosylation, and delivery to the cell surface.[115]

As professional APCs, DC subsets express specific forms of immunoproteasomes that generate a different spectrum of peptides from the standard proteasome and broaden the repertoire of antigens presented to cytolytic $CD8^+$ T cells. Transformed or infected cells also display peptides from modified self or exogenous proteins on their class I MHC molecules in order to be recognized by the TCR of activated cytolytic T cells for degradation. However, antigen-specific naïve $CD8^+$ T cells cannot directly eliminate transformed or infected cells; they must be activated by APCs such as DCs. To activate $CD8^+$ T cells, DCs must process antigens from infected or transformed cells, and even self-antigens, and present them through canonical class I MHC presentation or though "cross-presentation," which is described in the next section.

**Class I Cross-Presentation.** DCs can acquire antigens exogenously and process them for presentation by class I MHC molecules, which is referred to as *cross-presentation*.[9,32] This property is atypical because class I MHC molecules exclusively present endogenous proteins in most cells. Although the precise mechanism of cross-presentation remains controversial, it is well established that DCs use this process to activate $CD8^+$ T cells. DCs acquire antigens by endocytosis in the form of apoptotic cells, necrotic cells, antibody-opsonized cells, immune complexes, heat shock proteins, and exosomes, and even by nibbling of live cells.[9,32] In the same way, autophagosomes are another source of peptides for class I MHC molecules. The process of autophagy normally clears ubiquitinated cytoplasmic protein aggregates.[61] TLR activation or exposure to stress also induces DC aggresome-like structures (DALIS) containing polyubiquitinated protein, and peptides derived from DALIS can be presented by class I MHC molecules.[116]

Two main intra-cellular pathways traffic exogenous antigens from phagolysosomal compartments to the ER for cross-presentation. The cytosolic cross-presentation

pathway relies on antigen processing by the proteasome coupled to transport to the ER by TAP1 and TAP2 transporters. This pathway is sensitive to proteasome inhibitors. In contrast, the vacuolar pathway is resistant but is sensitive to inhibitors of lysosomal proteolysis.[9,32] Vacuolar cross-presentation is also less susceptible to TAP gene knockout in mice. The mechanism of transfer of antigens from phagosomes to class I MHC loading compartments has yet to be elucidated; however, it has been observed that high pH and low proteolytic activity favor the atypical class I MHC cross-presentation of phagocytosed antigens.[114,117] Recently, progress has been made in better understanding the cross-talk between the different cellular compartments that regulate the cross-presentation. Nair-Gupta and collaborators[118] have identified an important role in DCs for communication between the endosomal recycling compartment (ERC), which is a key reservoir of class I MHC molecules, and the phagosome in cross-presentation. Trafficking from the ERC to phagosomes is controlled by the TLR-MyD88-IKK2 pathway, which stabilizes membrane interactions between the phagosome and the ERC, ensuring that ERC-deployed class I MHC are specifically routed to phagosomes engaged in TLR signaling. On the other hand, the class I MHC peptide loading complex (PLC) is recruited from another subcellular compartment, the ER and Golgi intermediate compartment (ERGIC), in a TLR-independent manner. The highly coordinated trafficking from ERC and ERGIC delivers essential components for cross-presentation to phagosomes during infection, and control of the ERC pathway by TLR signals favors phagosomes that contain microbial proteins for cross-presentation in the context of TLR-primed T cell co-stimulation.[118]

### Class II Major Histocompatibility Complex Antigen Presentation

The class II MHC pathway is constitutively expressed only by APCs. Class II MHC α/β heterodimers rely on a specialized type II transmembrane chaperone protein, the invariant chain (Ii), for stable assembly in the ER. Ii stabilizes the class II MHC complex and contains an endosomal sorting and retention signal.[119] Class II MHC molecules are then transported and concentrated in multivesicular and multilamellar late endosomal compartments called class II MHC–containing compartments (MIICs). Antigens are endocytosed or autophagocytosed and retained within late endosome or phagosomes before fusing with lysosomes to form phagolysosomes. Concomitant TLR signals induce activation of the vacuolar proton pump that enhances lysosomal acidification and antigen proteolysis into antigenic peptides within phagolysosomes.[120] Acidification of this compartment allows optimal activity of cathepsins. Cathepsin S degrades the cytoplasmic tail of Ii, leaving a short peptide, the class II MHC–associated invariant-chain peptide (CLIP), bound to the peptide-binding groove and thus protected from proteases. CLIP is replaced by an antigenic peptide through the action of the catalyst-chaperone protein HLA-DM, which accelerates the rate of CLIP release, and the loaded class II MHC molecules are thought to be transported through cytoskeletal tubular structures that are directed toward the site of T cell interaction at the plasma membrane.[121]

TLRs regulate phagosome maturation,[74] enhance lysosomal acidification,[120] and increase antigen uptake transiently.[72] Class II MHC surface expression and turnover rates are regulated by cytoplasmic domain ubiquitination in DCs.[122] This mechanism explains the expression of low levels of class II MHC molecules by immature DCs and their increase in half-life after maturation, sustaining antigen presentation after migration into secondary lymphoid organs.

RA is characterized by autoantibodies against citrullinated proteins. A possible mechanism of generation of the immune response against citrullinated proteins has been described in mice.[123] It has been shown that two distinct conformers of MHC-peptide complexes are known for the same peptide; these conformers are referred to as type A for stable conformation and type B for less stable conformation. Peptides generated from intact protein are loaded onto class II MHC complex in the late endosome/lysosome. In this compartment, HLA-DM catalyzes peptide loading and acts as a conformational catalyst, and hence only more stable type A conformers are loaded. In comparison, the same peptide may be loaded exogenously at the cell surface and in the early endosome in exchange for poorly binding peptides occupying class II MHC molecules in the absence of HLA-DM. These mechanisms of loading give rise to both stable type A and flexible type B conformers. Hence only type A T cells are primed with native protein, and exogenous peptide gives rise to priming of both type A and B T cells. In the thymus, T cells recognizing the type A conformation for a peptide are deleted, whereas type B T cells escape thymic negative selection.[123] Thus self-reactive type B T cells are present in the naïve peripheral repertoire and have potential for autoimmune activation. This was recently shown in nonautoimmune-prone mice after immunization with unmodified hen egg lysozyme (HEL); T cells specifically reactive to citrullinated epitopes of HEL were present among the responding repertoire to immunization. The citrullinated HEL epitopes were processed and loaded onto class II MHC complexes and were presented to T cells by DCs.[124] Hence naturally occurring self-reactive T cells, which have evaded thymic negative selection, may recognize citrullinated peptides loaded as flexible type B conformers onto class II MHC molecules and subsequently provide help for B cell–mediated antibody responses against citrullinated proteins.

**Class II Cross-Presentation.** There is also a cross-presentation mechanism that allows the presentation of intra-cellular self-antigens on class II MHC to activate $CD4^+$ T cell responses. This process relies on autophagy, wherein cytoplasmic antigens are acquired and loaded onto class II MHC molecules in the autophagolysosome.[125]

### Lipid Presentation

CD1 molecules present lipid antigen to T cells. The CD1 family of class I MHC–like glycoproteins includes CD1d on the surfaces of DCs and CD1e, which remains in the endoplasmic reticulum. CD1a, CD1b, CD1c, and CD1d-restricted T cells express CD4 or CD8 or lack both CD4 and CD8 (double negative). By contrast, most CD1d-restricted T cells express a semi-invariant TCR and markers of NK cells and are identified as invariant NK T (iNKT) cells.[126]

Similar to class I MHC and class II MHC molecules, CD1 molecules assemble in the ER, where they noncovalently bind the chaperones calnexin, calreticulin, ERp57, and β2-microglobulin.[127] Lipid antigens are generated by lysosomal hydrolases of internalized phagosomes, membrane-bound lipids in clathrin-coated vesicles, or internalized apoptotic bodies or exosomes and are loaded onto CD1 molecules in the lysosomal lumen.

## T Cell Activation

cDCs interact with naïve T cells upon arrival in the lymphoid organs and with effector memory T cells at inflammatory sites. Exposure to the environment induces DC-derived signals that determine the outcomes of these interactions, which include the following: antigen presentation in the context of MHC molecules (signal 1), co-stimulatory molecules, including CD80 and CD86 (signal 2), and cytokines (signal 3). Some cell surface molecules are inhibitory, such as PDL1, which interacts with T cell PD1, or CD80/CD86, which interacts with T cell cytotoxic T lymphocyte–associated antigen 4 (CTLA-4). Signal 3—provided in cis by APCs to antigen-specific T cells—includes IL-12, IL-23, TNF, IL-6, IL-1β, and type I IFN produced by DCs. Because cytokine secretion varies according to PRR activation, PAMPs and DAMPs are important factors that can skew the adaptive immune response.

T cell activation depends on the intensity and length of DC–T cell interactions, mediated by the immunologic synapse (IS), which is a region of spatially and temporally organized motifs of membrane proteins and cytosolic molecules formed at the interface between a T cell and a DC. Stable long-lasting contacts of APCs with T cells are dependent on co-stimulatory molecules and integrin molecules ICAM-1 and ICAM-3. These integrins form a ring in the outer part of the IS, in a region adjacent to the corresponding area containing lymphocyte function–associated antigen-1 (LFA-1).[128] It is hypothesized that the stability of the IS confers temporal inhibition of DC apoptosis, which would enhance activation of clonal T cells in the lymph node.[127]

$CD4^+$ Th cells play a vital role in the induction of humoral and cellular immunity, providing signals for the activation of B cells and $CD8^+$ T cells. Controlled by the activated DCs, $CD4^+$ T cells can differentiate into Th1 cells, producing IFN-γ and IL-2; Th2 cells, producing IL-4, IL-5, and IL-13; Tfh cells, expressing inducible T cell co-stimulator and producing IL-21; Th17 cells, producing IL-17; or Tregs, producing TGF-β or IL-10.

DCs promote a Th1 phenotype by acting on both NK cells and naïve $CD4^+$ T cells. Collaboration of IFN-γ and IL-12 induces and sustains Th1 differentiation. The Th2 response is promoted by induction of OX40 ligand (OX40L) on DCs, which is mediated by release of thymic stromal lymphopoietin (TSLP) by epithelial cells, mast cells, and basophils.[129] Absence or depletion of IL-12 production by DCs also skews the T cell response to Th2. In turn, IL-10 secretion by Th2 cells can negatively regulate DC function. DCs make a deficient response to TSLP stimulation in Crohn's disease, an inflammatory bowel disease associated with Th1 and Th17 immunity.[130]

Pro-inflammatory Th17 cells expressing IL-17 and the RAR-related orphan receptor γ (RORγt) transcription factor were described in RA synovium.[131] Upon TLR stimulation, innate immune cells, including DCs, secrete IL-6 and IL-1β. The presence of IL-6 and TGF-β induces Th17 differentiation, subsequent production of IL-21, and expression of IL-23R. IL-21 amplifies Th17 differentiation; however, IL-23, which is produced by DCs, is needed for the maintenance of Th17 cells.[132]

IL-1β is a critical amplifier of Th17 differentiation, especially in humans. IL-1β and IL-6 also promote the reprogramming of forkhead box $P3^+$ ($FoxP3^+$) Tregs to Th17.[133] This scenario is relevant to the development of autoimmune disease, because Tregs are selected on the basis of intermediate affinity for self-peptides in the thymus.[134]

Although Th1 cells were the major subset of T cells identified in RA synovium, identification of Th17 cells and the cytokines IL-17 and IL-23 within affected tissues and/or fluids has implicated both Th1 and Th17 cells in the pathogenesis of both RA and spondyloarthropathy.[132,135] Synovial tissue DCs express IL-12p70 and IL-23p19, providing a mechanism by which Th1 and Th17 cell production is locally perpetuated.[136]

Tfh cells are induced by IL-6 and IL-21, which induce expression of CXC chemokine receptor 5 (CXCR5) to enable the migration of T cells into B cell follicles. They express B cell lymphoma 6 (Bcl-6), a master transcription factor for Tfh cell differentiation. Tfh cells also produce IL-21, which can induce affinity maturation and somatic hypermutation and increase memory B cell and long-lived plasma cell activity in germinal centers (GCs). However, abnormally activated Tfh or the lack of tolerogenic regulatory Tfh give rise to an immune reaction against autoantigens, which may occur in autoimmune diseases such as SLE and RA.[137]

pDCs, which are potent producers of type I IFN, also present viral and tumor antigens to initiate both $CD4^+$ and $CD8^+$ T cell responses, thereby providing an important link between innate and adaptive immunity.[138,139] Increased production of IFN-α may activate $CD8^+$ T cells, which are increased in kidneys in persons with lupus nephritis.[140,141] In addition, pDCs can induce Treg generation by induction of IDO (discussed later).

## B Cell Activation

B cells express both antigen-specific B cell receptors (BCRs) and various TLRs, thus allowing them to play a role in innate and adaptive immunity. Although DCs present processed antigens to naïve T cells, B cells recognize antigen in its unprocessed native state. Two mechanisms of resistance to intra-cellular antigen degradation in DCs are described: (1) the internalization of antigen-containing immune complexes into nondegradative intra-cellular compartments through FcγRIIB, followed by receptor recycling to the cell surface and presentation to the BCR[103]; and (2) accumulation of intact antigen in neutral endosomes by DC-SIGN (carbohydrate-containing antigen).

When DCs and B cells take up the same antigen, DCs can activate B cells in an antigen-specific $CD4^+$ T cell–dependent manner. This action results in B cell activation and isotype switching to IgG, IgA, and IgE, as well as

memory B cell generation in response to T-dependent antigens.

DCs can also stimulate B cell proliferation by expression of B cell–activating factor (BAFF) and its closely related tumor necrosis family member APRIL (a proliferation-inducing ligand).[142] Furthermore, inflammatory cytokines secreted by DCs can also affect B cell activation. IFN-α and IL-6, or ICAM-1, expressed by activated pDCs, regulate B cells to differentiate into plasma cells for T cell–independent antibody production.[143] IFN-α can enhance antibody secretion in vivo[144] and can induce cDCs to produce BAFF and APRIL, which triggers isotype switching independently of CD40 ligation.[145]

### Natural Killer Cell Activation

DCs can induce activation and/or proliferation of NK cells, resulting in increased NK cell cytolytic activity and/or IFN-γ production.[146] Both cell-cell contact–dependent interactions and soluble cytokine signals are involved. NKG2D ligands are cell contact–dependent signals expressed by DCs in response to stressful stimuli. LFA-1/ICAM-1 interactions have also been implicated in NK cell activation by DCs. Type I IFN augments NK cell cytotoxicity; IL-12 induces IFN-γ secretion and cell proliferation; IL-15 determines cell differentiation and survival; and others such as IL-18 and IL-2 are mediators in DC-mediated NK cell activation.

Reciprocally, NK cell–mediated activation of DCs depends mainly on cytokines, principally TNF and IFN-γ, whereas cell contact–dependent interactions are required for DC elimination. NK cells can lyse immature DCs (imDCs) through NKp30—a process referred to as *DC editing*.[147] A TNF-related apoptosis-inducing ligand (TRAIL)–mediated mechanism and CD94-NKG2A–mediated signals also induce DC lysis.

## DENDRITIC CELLS AND TOLERANCE

Self-tolerance is the essential process by which the immune system can discriminate self from nonself and remain anergic to the body's constituents (self-/endogenous antigens) while dealing with nonself/exogenous antigens such as invading microorganisms (pathogenic antigens). Central tolerance occurs in the thymus with the negative selection of thymocytes that react to self-antigens. Peripheral tolerance is the process by which autoreactive T cells that have escaped thymic selection can be anergized or deleted. It also includes the induction of Treg cells. Finally, the MPS, including DCs, regulate tissue homeostasis, which is key to maintaining peripheral tolerance.

### Central Tolerance

Central (or thymic) tolerance defects are important and are probably essential contributors to spontaneous autoimmune disease.[148] T cells are selected in the thymus according to their affinity for self-MHC molecules that are loaded with endogenous self-antigens displayed by thymic cortical epithelial cells. The T cells that are reactive to self-antigen above a threshold of affinity for self-antigen–MHC complexes expressed and presented by medullary APCs are then deleted by negative selection. In the thymus, medullary thymic epithelial cells (mTECs) are primarily responsible for negative selection because they express many self-antigens. mTECS express the transcription factor autoimmune regulator (AIRE), which drives the expression of self-antigens for presentation to thymocytes. It has been proposed that thymic DCs acquire those self-antigens either directly or indirectly from mTECs by phagocytosis of apoptotic mTECs, through exosomes trafficking between the two cell types, or through membrane exchanges by trogocytosis. Thymic lymphoid DCs, by cross-presenting those self-antigens, can supplement self-antigen presentation mediated by mTECs and contribute to the negative selection. Furthermore, the interaction between mTECs and thymic DCs leads to the generation of tolerogenic Tregs specific to autoantigens. In addition to thymic cDCs, peripheral migratory DCs such as pDCs can migrate in steady state from tissue to present self-antigens in order to induce clonal deletion of T cells and induce Treg generation.

### Peripheral Tolerance

Peripheral tolerance mechanisms provide a second level of control to restrain potentially autoreactive T cells that escape thymus negative selection and migrate to the periphery. Central tolerance is stochastic because it relies on the affinity threshold between TCRs and self-antigens; some autoreactive T cells can therefore escape. As for central tolerance, the direct function of DCs in peripheral tolerance remains incompletely understood. Studies targeting specific DC subsets in vivo in the mouse by injection with self-antigenic peptides fused to recombinant Fab fragment of antibodies against innate immune endocytic receptors, such as the CLR DEC205 (CD205,Ly75) or DCIR2/33D1,[149,150,151] have shown that DEC205 targeting generates tolerance in autoimmune murine models, such as experimental autoimmune encephalomyelitis (EAE), diabetes, and arthritis.[152,153]

A genetic approach restricting antigen expression on DC in mice showed that steady-state, high-level presentation caused drastic and stable unresponsiveness of antigen-specific $CD8^+$ T cells.[64] The peripheral CD8–T cell inhibition was mediated by the upregulation of the inhibitory co-receptors programmed cell death protein 1 (PD-1) and CTLA-4. Thus DCs can induce peripheral T cell tolerance to immune-dominant antigens that are expressed at high levels; however, the relevancy of these models to endogenous self-antigens and negative selection remains uncertain.

DCs have been also associated with the peripheral tolerance by facilitating the homeostasis of peripheral Tregs. DCs induce Treg cells in the presence of strong anti-inflammatory stimuli such as TGF-β and retinoic acid (RA),[154-157] and can support the proliferation of $Foxp3^+$ Treg cells after their depletion in vivo.[158] Migratory cDCs, but not resident lymphoid cDCs, induce the development of induced Treg cells specific for a particular self-antigen and can induce a specific tolerogenic response that could protect against induced autoimmune syndromes such as EAE or RA.[159,160] Finally, pDCs and cDCs produce tolerogenic factors, such as IDO, that negatively regulate T cells

by starving them of tryptophan, an essential amino acid required for cell growth and viability, and promoting the generation of FoxP3$^+$ Tregs with timing that ensures regulated expansion of activated T cells and other innate inflammatory pathways.[161,162] In the same way, DCs can produce IL-27, which in a CD39-dependent manner regulates the inflammasome and Th1 and Th17 T cell activation.[163]

Similar to central negative selection mediated by the mTECs, CD8$^+$ autoreactive T cells can be inhibited or deleted by radio-resistant lymph node stromal cells (LNSCs) via direct presentation of class I MHC self-antigens to autoreactive CD8 T cells[164] in a process relying on cell contact, such as by trogocytosis, and also on the production of exosomes.[164] The interaction with CD4$^+$ T cells induces their anergy and affects their survival.

It is unclear if actual tolerogenic subsets of DC exist or if their tolerogenic function is conditioned by their functional state because genetic or epigenetic evidence for tolerogenic DC subsets is still lacking. Deficiencies in certain signaling molecules have been shown to regulate some aspects of the tolerogenic function of DCs. These pathways primarily act through affecting the size of the DC compartment or the extent of DC activation. NF-κB activity is a key regulator of the DC functional state. Tolerance at some point relies on the activation of this pathway because NF-κB1 and p50 (active forms of NF-κB) deficiency in DCs favors autoimmune responses by deregulating the immunogenicity and life span of DCs.

A deficiency in DCs of A20, a ubiquitin-editing enzyme implicated in the degradation of various signaling molecules that activate NF-κB signaling, or the disruption of CD31, which is a co-inhibitory receptor of the NF-κB pathway, induces immunogenic DC development and autoimmune disease.[165,166] CD31 regulates the NF-κB pathway through the activation of the protein tyrosine phosphatase-1 (also known as Src homology region 2 domain-containing phosphatase-1 [SHP1]).[167] Similarly, the deficiency of SHP1, the kinase lyn, signal transducer and activator of transcription 3 (STAT3), or SOCS-1, which all negatively regulate the NF-κB pathway, also lead to auto-inflammation or autoimmunity.[148] In fact, inhibition of NF-κB and Notch1 by miR-23b promotes murine tolerogenic DCs in vitro, and in the absence of RelB (one of the members of the NF-κB transcription factor family), antigen-exposed DCs induce antigen-specific Tregs and suppress induced autoimmune syndrome after adoptive transfer into wild-type hosts.[168]

The mammalian target of rapamycin (mTOR) has also been implicated in DC-induced tolerance. DCs generated in the presence of rapamycin, an inhibitor of mTOR, induced antigen-specific Tregs and suppressed rejection after adoptive transfer into allograft recipients.[168a] The wingless type (Wnt)/β-catenin is a third major regulatory pathway involved in DC function.[169] β-Catenin was shown to be constitutively active in intestinal DCs and to regulate the balance between Foxp3$^+$ Tregs and Th17 effector cells in the lamina propria through induction of retinal dehydrogenase. Finally, enhanced and prolonged extra-cellular regulating kinase (ERK) signaling has also been shown to be important for suppression of IL-12 and induction of IL-10 secretion by DCs, which promote tolerance.[170]

In the steady state, DC tolerogenic function remains elusive, because constitutive DC ablation causes only a small reduction in T cell numbers without any obvious functional consequences upon autoreactive T cell activation.[171] Another study has claimed that constitutive ablation of DCs leads to autoimmune manifestations[172]; however, this study did not distinguish between T cell hyperproliferation and autoimmune disease induction. It is more likely that the autoimmune diseases emanated from a myeloproliferative syndrome caused by Flt-3-L accumulation in the absence of DCs.[173-175]

## AUTOIMMUNITY

In autoimmune diseases, clearance of self-antigens and/or tolerance against self-determinants are impaired. Activated autoreactive T cells, B cells, innate immune cells, and parenchymal cells participate in the process of tissue damage. DC antigen presentation can promote the priming and/or the effector differentiation of autoreactive T cells, either because of inappropriate activation signals or because of a cell-intrinsic breakdown of negative regulation, as previously described. Locally they act as both APCs and effector cells, producing pro-inflammatory molecules and regulating other effector cells. In different autoimmune conditions, cDCs and pDCs are enriched in inflamed tissues, particularly in a perivascular distribution. Moreover, DCs infiltrate tissues at very early stages of disease and contribute to the recruitment and organization of other immune cells. For example, in mice, DC infiltration is an early feature of islet cell autoimmunity in diabetes mellitus and contributes to local lymphoid tissue formation in the pancreas.[176,177] Organization of tissue into lymph node–like structures, including lymphoid follicles, is a common feature of tissues affected by autoimmune inflammation,[178,179] which contain follicular DCs (FDCs) and nurse-like fibroblast-like synoviocytes, supporting chronic production of autoantibodies.[180]

Here we discuss prototypic autoimmune diseases associated with rheumatoid disorders and the role that DCs play in their initiation and progression.

### Dendritic Cells in Psoriasis

Psoriasis is a chronic inflammatory skin disease that is characterized by the thickening of the epidermis as a result of the hyperproliferation and abnormal differentiation of keratinocytes. The causes of psoriasis and psoriatic arthritis are not yet fully understood; it is thought that primary infection by bacteria may initiate the development of the chronic autoimmune disease. In psoriatic plaques, the local inflammation is driven by activated keratinocytes that express anti-microbial peptides, chemokines, and growth factors and drive the recruitment of inflammatory innate immune effectors.

Dermal DC infiltration is increased in psoriatic skin and is associated with proliferation of autoreactive T cells, inducing a Th1 response.[181] A subset of dermal infDCs, known as Tip-DC, produces inducible nitric oxide synthase (iNOS) and TNF, promoting a pro-inflammatory environment. In addition, it has been shown that effector Th17 and potentially skin γδ T cells that produce IL-17 and IL-22 have a major role in psoriatic inflammation.[182,183] In

psoriatic lesions, a vicious cycle develops in which activated T cells produce inflammatory cytokines such as TNF and IFN-γ, which in turn activate keratinocytes to produce a wide variety of cytokines and chemokines, resulting in DC activation. The latter mechanism leads to a larger recruitment of inflammatory T cells. Although the trigger remains unknown, considering the effector T cell component of the disease, it is highly suspected that APCs play a key role in psoriasis development.

One experimental model of psoriasis-like inflammation has emerged after repeated application of Aldara, a cream containing the TLR7 ligand imiquimod, to mouse skin.[184] The contribution of TLR7 ligand in this model remains unclear because experimental psoriasis also seems to be induced by the vehicle independently of imiquimod and TLR7 stimulation but in an inflammasome-dependent manner.[185] Because both TLR7 triggering and inflammasome activation induce a strong inflammatory response, they may have a redundant or synergistic function in driving experimental psoriasis in mice. In another model, after treatment with imiquimod, mice in which MYD88 expression is restricted to $CD11c^+$ cells developed identical psoriatic symptoms as wild-type mice, which highlights that $CD11c^+$[186] DCs are sufficient to prime psoriasis development. In addition, it was shown that DC depletion in CD11c–diphtheria toxin receptor (DTR) mice protects against the development of psoriasis plaques in mice. In this study, it was proposed that IL-36 produced by skin cells induced DCs to produce IL-23 and to drive Th17 cell differentiation.[187] In fact, it has been shown that the selective expression of TLR7 signaling in specific DC subsets differentially contributes to the disease development. Restricted expression of TLR7 to $CD207^+$ (langerin) cDCs such as LCs resulted in attenuated disease and a more tolerogenic environment, which suggests that it is the $CD207^-$ dermal cDCs and moDCs that are essential to prime the imiquimod-induced psoriasis in mice. Dermal $CD207^-$ DCs secrete IL-23, which promotes dermal T cell activation and production of IL-17 and IL-22.[188]

Upon treatment with systemic type I IFN, flares of psoriasis have been observed, suggesting that type I IFN contributes to psoriasis development. Type I IFN–producing pDCs were therefore also proposed to have a major role in the initiation of psoriasis.[189] pDCs are recruited to the skin through the production of chemerin in inflamed skin and the chemokine-like receptor 1 (CMKLR1/ CHEMR23).[190] Activated keratinocytes produce anti-microbial peptide LL37, which has been shown to bind self–extra-cellular nucleic acids (DNA and RNA) that are generated in the skin during normal cell turnover or during injury and to trigger type I IFN in psoriasis.[191] LL37–nucleic acid particles can induce type I IFN production by pDCs and activate cDCs.[191-193] Surprisingly, pDC ablation did not affect the severity of the experimental psoriasis in mice,[188] which suggests that pDCS and type I IFN may instead contribute to the chronic aspect of the disease.

## Dendritic Cells in Systemic Lupus Erythematosus

SLE is often considered to be a systemic antibody-driven autoimmune disorder in which primarily nuclear components, such as DNA, histones, and riboproteins, are targeted. It is induced by the loss of tolerance to self-antigens, the accumulation of activated autoreactive T and B cells, and the abnormal production of cytokines. In SLE, microenvironmental and genetic factors may induce inappropriate self-antigen presentation by APCs such as DCs, leading to the abnormal activation of autoreactive T and B cell activation.

SLE is characterized by an increase of cell death and a significant decrease of dead cell clearance, which lead to the accumulation of autoantigens. In addition, it has been shown that phagocytic cells have a decreased ability to interact with and process dead cells.[194,195] Although the accumulation of dead cells contributes to disease development, it is not sufficient to induce autoimmune disease because vaccination with apoptotic cells/blebs does not induce adaptive immunity in the steady-state condition of non–lupus-prone mice, whereas necrotic and apoptotic cell exposure can lead to lupus development in SLE-prone murine experimental models.[196,197]

Neutrophil extra-cellular trap (NET)osis is a neutrophil specialized form of controlled cell death. During NETosis, the neutrophils extrude fibrillary networks composed of DNA, DNA-binding proteins such as histones, and also the content of their granules, such as anti-microbial peptides, neutrophil elastase, myeloperoxidase, and cathepsin G. NETosis is induced upon infection but also upon sterile inflammation, such as by TNF monosodiumurate and cytokines (IL-8, IL-1α, and IFN-I). SLE has been associated with a deficiency in clearance of the NETs. Some patients have a reduced DNAse-I activity, which is a key enzyme to digest extra-cellular DNA and degrade NETs. Those patients have significantly higher titers of autoantibodies targeted against dsDNA, similar to DNAse I–deficient mice that develop SLE-like syndromes.[198-201] Furthermore, DAMPs such as anti-microbial peptides and alarmins such as LL37 and HMGB1 tend to accumulate in NETs from SLE and contribute to disease development. An abundance of protein modifications exist, such as methylation, acetylation, citrullination, poly-ADP-ribosylation, and ubiquitinylation, in the cellular waste of nondegraded NETs and apoptotic cells; these modifications may give rise to neoantigens, which can be recognized as modified self.[202] It has been speculated that APCs such as DCs may cross-present these antigens to induce autoimmunity.

It is suspected that APCs are one of the key regulators of SLE development. Recent studies of the profile of maturation of the DC subset in patients with SLE have shown that both cDCs and pDCs have a more inflammatory activated phenotype and more efficiently prime T cell responses.[194] pDCs and inflammatory cDCs accumulate in nephritic kidneys and skin lesions of patients with SLE, but the role of DCs in SLE remains poorly understood. In the C57/BL6 murine background, the DC-restricted loss of Fas (CD95), a receptor of the family of TNFR implicated in apoptosis regulation, induces disease manifestations.[203] In fact, the most common experimental model for SLE are MRL mice, which express the lymphoprolipherative-deficient allele of the gene Fas (MRL-FasLpr). The constitutive deletion of DCs in the MRL mice decreases autoreactive T cell proliferation and plasmablast differentiation, which improves outcome of the disease.[204] Similarly, DC function has been

suggested by the DC-restricted deletion of negative regulators, which leads to the loss of tolerance and SLE-like disease in vivo. The DC-specific ablation of B lymphocyte–induced maturation protein-1 (BLIMP-1 or PRDM-1), which is a transcriptional repressor that controls the differentiation of B and T cells, induces an SLE-like syndrome in female mice.[205] Interestingly, human polymorphisms of the *PRDM1* gene have been associated with SLE, and SLE incidence is higher in women. In mice, the DC-restricted deficiency of PRDM1 results in higher IL-6 production and Tfh cell differentiation that enhances B cell germinal center formation and induces humoral autoreactivity. In humans, both heterozygote or homozygote loss of PRDM1 in DCs induces the same phenotype in vitro, clearly suggesting that abnormal activation of DCs correlates with a loss of tolerance and a higher susceptibility to SLE.

Type I IFN is known to be associated with the exacerbation of SLE disease parameters. A leukocytic interferon-stimulated gene (ISG) expression signature in patients with SLE correlates with disease outcome.[206] Type I IFNs might promote SLE by inducing the maturation of monocytes, the stimulation of autoantibody production by B cells, and NETosis. Indeed, inhibition of type I IFN signaling in mice improves SLE development, such as in the New Zealand black/New Zealand white (NZB/NZW)–derived SLE-prone experimental model.[207,208] pDCs are recognized as the type I IFN professional producer, and these cells have been proposed to be an important source of aberrant type I IFN secretion and major drivers of SLE progression. Patients with SLE have reduced numbers of pDCs in the blood and an increased accumulation of pDCs in tissue lesions.[209]

pDCs express a specific profile of endosomal nucleic acid–sensing PRR such as TLR7, TLR8, and TLR9, whereas cDCs express TLR8. pDCs can be activated by self–nucleic acids bound to antibodies, or with DNA- or RNA-binding proteins such as HMGB1 or LL37, which accumulate in NETs.[210] These complexes induce pDCs to secrete type I IFN, which in turn can drive a vicious cycle by activating MPS and driving immune activation in patients with SLE.[211,212] The exact contribution of PRR remains poorly understood because TLR7 silencing in SLE-prone mouse models improves disease progression, whereas TLR9 and TLR8 silencing have an opposite effect and exacerbate the disease development.[213,214] Recently, it has been proposed that TLR8 and TLR9 restrain TLR7 silencing in cDCs and B cells, respectively.[215] Other studies seem to suggest that B cells and DCs contribute differentially via TLR signaling to SLE syndrome, with B cells being required for renal disease and autoantibody production, whereas DCs contribute to other aspects. Considering the Myd88 signaling activated by the TLR7 and TLR9, it seems that the B cells are contributing to SLE development, whereas DCs only contribute to some specific aspect of the disease, such as skin lesions.[216] Thus, in addition to other cell types such as B cells, pDCs and cDCs might represent a key component of SLE pathogenesis and may represent attractive therapeutic targets.

## Dendritic Cells in Rheumatoid Arthritis

RA is a chronic autoimmune disease characterized by severe inflammation of the synovial joints, causing cartilage breakdown and bone destruction. The precise cause of RA remains poorly understood, although autoreactive T cells contribute to disease pathogenesis. DCs are thought to initiate the inflammatory disease through presentation of autoantigens, as suggested by animal models of RA in which DCs have been depleted, or through pro-inflammatory and regulatory effector functions.

For instance, joint DCs and monocyte-derived DCs isolated from patients can present human cartilage glycoprotein 39 (HCgp39) and epitopes from synovial fluid (SF) to antigen-specific T cells, respectively.[217] Further evidence for the contributing role of DCs to disease initiation and perpetuation in RA and the spondyloarthropathies derives from the substantial accumulation of immature and mature DC subsets, including cDCs and pDCs perivascularly in inflamed synovium, in close association with T and B cell follicles.[218] This accumulation of DCs contains the most significant numbers of mDCs and pDCs identified in any human inflammatory site.[136,218,219] DCs identified in RA synovial tissue tend to be activated because they have heightened levels of MHC, CD86,[220] and RelB.[221] They also express the receptor activator of NF-κB (RANK) and its ligand (RANKL),[222] and finally, they produce more pro-inflammatory cytokines ex vivo (IL-1, IL-6, and TNF) in response to stimulation with ICs or TLR agonists.[223]

TLR8 is expressed by inflammatory cells such as DCs and myeloid cells in RA and systemic arthritis, such as Sjögren's syndrome and Still's disease. The recent generation of transgenic mice expressing the human TLR8 has highlighted the contribution of this PRR in the development of complex spontaneous autoimmune diseases, including systemic arthritis.[224] These DCs may have migrated into the joints in response to locally produced cytokines and chemokines (CCL19 to CCL21) or may differentiate locally from myeloid progenitors in response to growth factors contained within SF.[220,225] Ectopic expression of CCL19 may also induce the formation of lymphoid tissue similar to that seen in rheumatoid synovial tissue[226] and may therefore play a key role in RA development. In the peripheral blood of persons with RA and juvenile RA, cDCs were found to be reduced relative to healthy peripheral blood, and this reduction correlated with disease severity,[227-229] supporting the idea that migration to synovium is increased by inflammatory chemotactic activity. Furthermore, cDCs in persons with RA appear to be threefold to fourfold enriched in fresh SF compared with the blood and are more differentiated than are blood DC precursors.[230]

SF DCs and blood DCs stimulate resting allogeneic T cells with equivalent efficacy; however, SF DCs are markedly more efficient stimulators of autologous T cells in the absence of exogenous antigen, suggesting that their MHC molecules are loaded with relevant RA autoantigens.[231] RA was initially believed to be exclusively Th1 driven. However, identification of Th17 cells and the cytokine IL-17 within affected tissues and/or fluids now implicates both Th1 and Th17 cells in its pathogenesis.[131] DCs are required for the differentiation of both subsets from naïve precursors. Th1 cells, which produce IFN-γ, activate macrophages to produce pro-inflammatory cytokines (IL-1, IL-6, and TNF) and induce immunoglobulin class switching to complement-fixing antibodies. IL-17 recruits leukocytes and stimulates IL-1 and TNF production by human macrophages, which all together stimulate activation of synovial fibroblasts.

Th17 cells mediate bone destruction in RA by stimulating osteoclastogenesis through RANK-RANKL interactions.[232] Subsets of synovial DCs express the cytokines essential for full differentiation of Th1 and Th17 cells (IL-12 and IL-23, respectively), providing a mechanism by which their production is locally facilitated or perpetuated. Activated DCs can also produce the chemoattractant molecule CCL5 to promote the recruitment of inflammatory Th1 and Th17 T cells.[233] Anti-citrullinated protein antibodies (ACPAs) and rheumatoid factor antibodies are presumed to bind to FcRs on macrophages and DCs, thereby inducing their activation and production of pro-inflammatory cytokines.[234] It is possible that ectopic lymphoid organs that resemble GCs and support autoantibody production are local sources of these antibodies.[235]

Finally, pDCs have also been found in rheumatoid synovium, and through production of IFN-α, they may enhance autoantibody production.[236] The number of $CD304^+$ pDCs expressing type I IFN and IL-18 was found to exceed that of the $CD1a^+$ subset of cDCs expressing IL-12 and IL-23 in RA synovium, particularly in patients positive for rheumatoid factor and ACPAs.[136] pDCs also displayed immunoreactivity for IDO[237] and may contribute to tolerance deregulation.

Altogether, human data strongly suggest multiple roles for DCs in rheumatoid synovium, local inflammation, joint destruction, and immune regulation. These data complement murine studies of inflammatory arthritis, which establish the important role of DCs in priming, inflammatory responses, and regulation of arthritic autoimmune responses.

### Dendritic Cells in Sjögren's Syndrome

Sjögren's syndrome (SS) is a chronic disease of autoimmune origin that typically affects middle-aged women. Although SS is considered a rather benign disease, there is a risk that non-Hodgkin's lymphoma may develop in persons with SS. SS is considered an autoimmune disorder because glandular and extraglandular epithelia are the target of lymphocyte infiltration and tissue damage. SS affects secretory organs, mainly the salivary and lacrimal glands, and induces oral and ocular dryness. It is also associated with a broad range of clinical manifestations related to a more diffuse autoimmune syndrome.[238] Genetic, environmental (bacterial and viral infection), and hormonal factors seem to be responsible for the disease onset. SS and other autoimmune diseases have been associated with the autoimmune/inflammatory syndrome induced by adjuvants (ASIA), which is observed as a negative side effect of vaccination.[239]

In SS, tissue-infiltrating cells are mainly $CD4^+$ T cells and some $CD8^+$ T cells, B cells, and some plasma cells.[240-242] SS-related autoantibodies include SSA/Ro, SSB/La, antinuclear antibodies, and rheumatoid factor. GC formation with follicular lymphoid DC networks has been shown in the salivary glands of persons with SS,[243-245] possibly recruiting lymphocytes to the site. Follicular DCs have also been implicated as accessory cells for B cell function.[246] Recently, it has been shown that salivary gland epithelial cells induce Tfh cell differentiation in the glands of patients with SS.[247] The function of DCs in this process remains unclear, but like salivary gland epithelial cells, DCs express membrane-bound molecules such as inducible T cell co-stimulator ligand, which play a pivotal role in Tfh cell differentiation.[248] Mouse models of SS showed that DC infiltration precedes lymphocyte infiltration into the submandibular gland, suggesting the initiating role of DCs in disease development. Increased numbers of mature DCs were detected in a mouse model and in humans with SS.[249] Decreased levels of pDCs in the blood of persons with SS is associated with their recruitment and detection into salivary glands of persons with SS but not of healthy control subjects. Given the role of pDCs and the increased levels of anti-nuclear antibodies and of type I interferon in the salivary glands,[250-252] several studies have investigated the role of Epstein-Barr, hepatitis C, human T-lymphotropic virus type I, and coxsackie virus in patients with SS,[253-255] but no evidence has been found to support their direct involvement. Interestingly, IFN-related genes are induced in SS salivary gland tissues. In addition, it seems that some noncoding RNAs, such as long interspersed nuclear element 1 retroviral elements, tend to be overexpressed and correlate with the accumulation of type I IFN. These noncoding RNAs have been shown to be immunogenic and can be sensed as DAMPs or endogenous activator of TLR7, TLR8, and TLR9. In peripheral blood, in line with previous observations in lupus and other systemic autoimmune diseases, overexpression of IFN-inducible genes as a result of peripheral type I IFN activity in association with disease activity has also been detected. Altogether, these data implicate a role for DC subsets in SS development or exacerbation.

## CONCLUSIONS AND FUTURE DIRECTIONS

DCs are a heterogeneous population of bone marrow–derived mononuclear cells that are found in an immature state in virtually all tissues in the body. As professional APCs, DCs are key effectors of innate immunity that stimulate naïve T cells, as well as B cells and NK cells, and initiate immune responses. In this way they contribute to protection against infections, maintenance of homeostasis, and also maintenance and regulation of tolerance. Their roles in tolerance regulation suggest that they might be key effectors in the development of autoimmune diseases and inflammatory diseases and also in graft tolerance and rejection. In fact, DCs are involved in the progression and maintenance of autoimmune diseases and can modify both innate and adaptive immune responses to derive autoimmune pathology. In this way the function of the different DC subsets needs to be intensively investigated to be able to specifically target the subsets implicated in specific phases of development of autoimmune disease.

### Inflammation Resolution

One of the challenges in autoimmune diseases and chronic inflammatory diseases is to contain detrimental aspects of the immune response. Several approaches have been tried using nonsteroidal drugs, glucocorticoids, and disease-modifying agents of rheumatoid diseases.[256] Anti-cytokine therapies that block TNF or its receptors provide beneficial effects in RA, psoriasis, ankylosing spondylitis, irritable bowel disease, and Crohn's disease. Other cytokines have also been targeted, such as IL-1β and IL-6 in RA and

juvenile arthritis, IL-12 p40 (subunits of IL-12 and IL-23) in psoriasis, and IL-17 in psoriasis and autoimmune uveitis. IL-21 is another product of Th17 T cells that is implicated in B cell regulation. IL-21–blocking therapies are under development to be used against autoimmune and auto-inflammatory diseases. New treatments are also in development to target cytokine and growth factor receptor pathways. The inhibition of Janus kinase (1 and 3) interferes with activation, growth, and survival of immune cells and is being investigated through inhibitors to treat specific cases of RA.[257] Other drugs are under development to target other MAPK pathways, such as p38 MAPK, SYK, and phosphatidylinositol 3-kinases.

## Immune Response Activation and Co-stimulation

The interactions between CD80/86 on APCs and CD28 on T cells results in powerful co-stimulation. CTLA-4 is a negative regulator expressed at the surface of T cells. CTLA-4–Ig fusion protein, which binds CD80/CD86 at the surface of APCs, is actively being used to block the CD28-mediated co-stimulatory pathway in order to inhibit the activation of CD28-expressing T cells and contain the T cell–mediated autoimmune response. The agonist CTLA-4–Ig has been used successfully in RA, whereas anti–CTLA-4 antibodies are approved to treat advanced melanoma. It is possible that other co-stimulatory pathways may be amenable to manipulation in the treatment of autoimmune diseases, such as PD-1 and others. A final approach is to target immune cells with antibodies to induce their depletion; in this way, an antibody against CD52, which is expressed on lymphoid and myeloid cells, or against CD19 and CD20, which are expressed by B cells, may ultimately show effects in certain conditions.

## Vaccines and Cellular Immunotherapy

Autoimmune disease could be targeted by vaccines that restore specific tolerogenic responses and promote the negative selection of autoimmune T effectors targeting autoantigens. More research is required to identify immunogenic epitopes implicated in autoimmune diseases, to develop specific tolerogenic adjuvants, and to engineer new vehicles to target APCs, such as DCs, that can mediate tolerogenic response. Different vaccine approaches could be considered, such as generating tolerogenic DC vaccines against autoimmune epitopes in order to induce Tregs, regulate B cell responses, or restore peripheral negative selection. In that light, tolerogenic DCs pulsed with peptides from citrullinated proteins are being used to actively tolerize T cells in persons with RA.

In the era of immunotherapies, substantial progress has been made in understanding innate and adaptive immune responses and how they could be regulated and better targeted to contain immunopathologies, for example, to reduce graft rejection and graft-versus-host disease and improve autoimmune disease outcome.

CHAPTER 10

# Mononuclear Phagocytes

Siamon Gordon • Annette Plüddemann

**KEY POINTS**

- Mononuclear phagocytes, which include monocytes, macrophages, dendritic cells, and osteoclasts, play an important role in tissue homeostasis and in cellular and humoral innate and adaptive immunity.
- Macrophage populations in many tissues derive from yolk sac and fetal liver, which persist and proliferate in the adult.
- Resident tissue macrophages display marked phenotypic heterogeneity, depending on their local microenvironment.
- Postnatally, distinct subsets of bone marrow–derived monocytes are recruited to inflammatory tissue sites.
- Microbes and cytokines (e.g., interferon-γ, interleukin [IL]-4, and IL-10) regulate macrophage activation.
- Macrophages express a range of opsonic and non-opsonic receptors to recognize and take up foreign and altered host components.
- Toll-like membrane, nucleotide oligomerization domain (NOD)-like, and cytosolic nucleic acid receptors induce alterations in macrophage gene expression and secretion of inflammatory mediators.
- Macrophages and their products contribute to tissue damage and repair and to chronic inflammation and autoimmunity.

Mononuclear phagocytes are widely distributed, biosynthetically active cells originating in the yolk sac and fetal liver during development. These cells persist in many tissues as resident macrophage populations throughout adult life. Postnatally, the bone marrow contributes circulating monocytes, which enter tissues constitutively and in response to inflammatory stimuli, giving rise to macrophages, dendritic cells (DCs), and osteoclasts. In connective tissue and bone, these cells play a major role in homeostasis, growth, and remodeling as mature macrophages (Figure 10-1) and osteoclasts. Myeloid DCs represent a distinct form of differentiation and are specialized to maintain immune tolerance or to induce humoral and cellular immunity through B and T lymphocytes. Through their recognition, antigen-presenting, regulatory, and effector mechanisms, mononuclear phagocytes contribute to a range of inflammatory, infectious, autoimmune, metabolic, and degenerative rheumatic diseases, providing targets for therapeutic intervention.

Growth of knowledge in mononuclear phagocyte biology has developed in close association with understanding of the pathogenesis and treatment of chronic arthritis. Relevant examples include the development of steroidal and nonsteroidal anti-inflammatory agents and of anti–tumor necrosis factor (TNF) monoclonal antibodies.[1] Genetic lesions in macrophage colony-stimulating factor (M-CSF) cause osteoclast deficiency and osteopetrosis in mouse models, whereas human mutations in cytosolic nucleotide oligomerization domain (NOD)-like receptors (NLRs) result in interleukin (IL)-1β overproduction and hyperinflammatory syndromes[2] that are often associated with persistent joint disease. Immune complex deposition and complement activation combine with Toll-like receptor (TLR) recognition to induce effector pathways of tissue destruction and repair.

This chapter reviews general aspects of mononuclear phagocyte differentiation, recruitment, and activation, integrating the properties of different cellular subtypes. Studies on the biology of macrophages, DCs, and osteoclasts have diverged to the extent that common features have been overlooked in the understandable search for specificity. This review is an attempt, in part, to reintegrate these differentiated sublineages. General features especially relevant to physiologic and pathologic consequences of their presence in bone, joints, and connective tissues are discussed, and gaps in our knowledge are pointed out. The emphasis is on studies in humans, where available, with reference to murine models where applicable. The subject area encompasses innate and acquired immunity, autoimmunity, and *osteoimmunology*,[3] a reflection of local specialization of mononuclear phagocyte and lymphocyte biology. Relevant topics discussed elsewhere in this textbook include innate immunity (see Chapter 17), cytokines and chemokines (see Chapter 26), osteoclast functions (see Chapter 4), and anti-TNF therapy (see Chapter 63). For further details in connection with macrophage[4-8] and DC biology,[9-11] see reviews cited in this chapter.

## OVERVIEW

Recent studies in the mouse have demonstrated that resident macrophage populations in many adult tissues, including skin, brain, liver, and lung, derive from the yolk sac and fetal liver, persisting and turning over slowly as required. The bone marrow, which develops around birth, generates circulating monocytes that can also give rise to selected tissue macrophages—for example, in the gut—as well as newly recruited, "elicited" macrophages in response to a range of inflammatory and metabolic agents. Resident and elicited macrophages differ in turnover and phenotype, but both types display marked microheterogeneity in particular

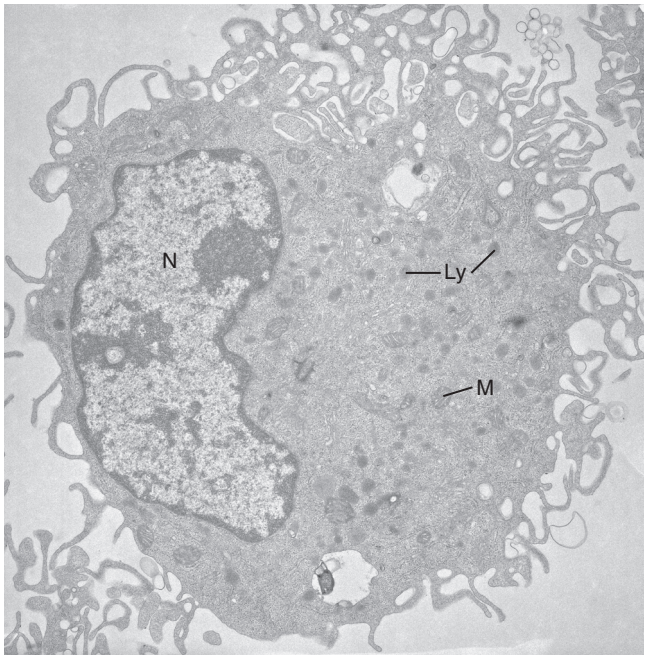

**Figure 10-1** Thin section of a bone marrow–derived mouse macrophage. Cells were cultured for 7 days and were fixed and processed for conventional electron microscopy. Ly, Lysosome; M, mitochondrion; N, nucleus. *(Courtesy Chantal de Chastellier, Centre d'Immunologie de Marseille-Luminy, Marseille, France.)*

tissue environments, such as brain and lung.[8] Similarly, and with some overlap in properties, myeloid DCs are present as heterogeneous resident sentinel cells at mucosal and cutaneous surfaces,[10-12] undergoing a complex maturation process as they migrate to lymphoid organs after capture of antigens. Monocyte-derived DCs are recruited to many tissues during infection as a result of antigenic stimulation. Plasmacytoid DCs may represent a distinct sublineage that is specialized to produce high levels of type I interferon (IFN) in response to viral stimuli. Poorly defined monocytic precursors in the blood give rise to multinucleated osteoclasts, which are specialized to resorb bone.[13]

Circulating monocytes are themselves heterogeneous, using distinct chemokine and adhesion receptors to give rise to different tissue mononuclear phagocytes.[14] These cells differ in life span depending on the recruitment stimuli and on local factors in their environment, and they express diverse plasma membrane receptors, making it possible for them to interact with many different cell types and with microbial and modified host components. Phagocytosis is a hallmark of the ability of macrophages and DCs to engulf particulates, including foreign materials, bacteria,[15] and dying host cells generated by apoptosis or necrosis.[16]

These particulates are recognized by non-opsonic receptors, including scavenger and lectin-like receptors, or after opsonization with antibodies or complement or both that enhance uptake via Fc and complement receptors. In addition, other humoral proteins, such as pentraxins, interact with their target ligands,[17] bridging them to less well-defined macrophage receptors, which regulate early cellular responses during innate immunity. TLRs play an important role in sensing the nature of the captured cargo, often interacting with the extensive repertoire of non-TLR receptors (NTRs). An extended family of NLRs senses various cytosolic ligands, resulting in a complex assembly of proteins (inflammasomes), caspase activation, and release of IL-1β.[18] Recent studies have defined additional complex sensors of nucleic acids in the cytoplasm.[19]

Uptake of particulate and soluble antigen, directly or by "cross-priming,"[20] induces DC maturation, processing, and association with class II major histocompatibility complex (MHC) molecules, as well as presentation of peptides to naïve CD4 T lymphocytes. Endogenously generated or foreign peptides generated during biosynthesis of virus glycoproteins associate with class I MHC molecules for surface recognition by cytotoxic T cells (mainly CD8). DCs and possibly macrophages regulate T cell activation or tolerance through additional co-stimulatory surface antigens and cytokines, depending in part on concomitant TLR stimulation. Activated T lymphocytes and their products, such as IFN-γ, IL-4/IL-13, and IL-10, regulate the effector functions of mononuclear phagocytes.

Digestion of macromolecules, which occurs in the vacuolar compartment, involves dynamic membrane traffic and interactions with the cytoskeleton. Complex intra-cellular pathways transduce surface and vacuole-derived stimuli to initiate formation of intra-cellular protein signaling complexes. Transcription factors translocate to the nucleus and form activation or inhibitory chromatin-binding complexes that regulate gene expression and biosynthesis of secretory products, such as TNF. Low-molecular-weight metabolites are generated by nontranscriptional mechanisms, yielding inflammatory mediators and anti-microbial activities. Osteoclasts are able to secrete hydrochloric acid and potent proteolytic enzymes into sealed-off localized areas of bone, to which they adhere tightly through specialized podosomes and actin rings.

The secretory activities of mononuclear phagocytes influence a range of cellular and extra-cellular targets to maintain tissue homeostasis but also are responsible for tissue destruction. Their trophic actions,[21] through cellular contact with other stromal cells and extra-cellular matrix and secretion, regulate tissue catabolism, cell growth, angiogenesis, and repair. In addition to local effects, macrophages contribute to systemic integration of pro-inflammatory and anti-inflammatory effects, acting on the central nervous system, endocrine organs, liver, and energy stores.

Overall, the activation phenotype of mononuclear phagocytes is modulated by extrinsic factors (e.g., cytokines and hormones), balance of surface receptors with activating/inhibitory cytoplasmic motifs, cytosolic regulators such as suppressors of cytokine synthesis (SOCS)[22] proteins, phosphorylation/dephosphorylation of signaling molecules, assembly of transcription factor complexes on chromatin, and epigenetic mechanisms such as histone and DNA methylation and acetylation. Microarray analysis of macrophages has made it possible to distinguish characteristic signatures of gene expression after innate activation via TLRs, deactivation via glucocorticoids, or modulation via cytokines. As a result, the phenotype of tissue macrophages is markedly heterogeneous, making for complexity of function in different sites in health and disease, but also providing opportunities for novel state-specific or tissue-specific targeting by drugs.

## LIFE HISTORY AND HETEROGENEITY (MACROPHAGES, DENDRITIC CELLS, AND OSTEOCLASTS)

In the adult, all three sublineages of mononuclear phagocytes originate from $CD34^+$ committed progenitor cells in the bone marrow. These cells diverge from lymphoid cells and subsequently from polymorphonuclear leukocytes, although many genes are still expressed but not translated in both neutrophils and monocytes/macrophages. Monocyte-derived DCs also express many genes in common with macrophages, although they can be distinguished by microarray analysis. In vitro, bone marrow precursors and blood monocytes can be stimulated by growth factors[23] to generate macrophages (M-CSF or granulocyte-macrophage colony-stimulating factor [GM-CSF]), DCs (GM-CSF, with or without IL-4), or osteoclasts (M-CSF and receptor activator of nuclear factor-κB [NF-κB] [RANK] ligand). Some of these growth factors also are essential in vivo (e.g., osteopetrotic, M-CSF–deficient mice lack many but not all populations of tissue macrophages and osteoclasts).[24,25] Monocytopoiesis is less well understood in humans and may depend on M-CSF and GM-CSF. Trophic interactions between hematopoietic precursors and stromal cells in the bone marrow (which are mesenchymal and hematopoietic in origin) are mediated by cell contact, via surface receptors,[21] and by soluble factors (e.g., c-Kit ligand and IL-1). Transcription factors that are essential for monocyte/macrophage production and related cells include Pu-1, other Ets family members, Maf,[26] Mi, which is implicated in microphthalmia, and GATA6, which is associated with resident peritoneal cells.[27,28] DCs express a unique transcription factor, ZDC.[29]

Although bone marrow precursors proliferate vigorously as they differentiate in the presence of M-CSF or GM-CSF, monocytes become refractory to these growth stimuli. Local macrophage proliferation can be induced by IL-4 during Th2 inflammation.[30] Restriction of DNA synthesis is associated with chromatin condensation, whereas RNA and protein synthesis persists and can be modulated by a variety of stimuli, as will be discussed further.

Tissue macrophages, DCs, and osteoclasts all derive from circulating monocytes, although these already may display heterogeneity (Table 10-1). Recent studies in transgenic mouse models and in humans have described progenitor cells and precursor-product relationships in monocyte-macrophages, as well as DC differentiation.[12] Cells are recruited constitutively to peripheral sites in the steady state. A subset of patrolling monocytes may not leave the vasculature in the steady state. Additional monocytes can be recruited to local sites in response to infectious, inflammatory, and metabolic stimuli. Such "elicited" cells display distinct properties from the "resident" cells, which, in the case of macrophages and DCs, also display marked diversity, depending on their location. A considerable body of evidence indicates that different subsets of macrophages and DCs originate from distinct monocyte populations in peripheral blood.[31-34] Apart from marker antigens (e.g., CD14, the receptor for lipopolysaccharide (LPS)-binding proteins, and Gr-1, a mouse Ly-6 antigen expressed by polymorphonuclear neutrophils and by some monocytes), levels of chemokine receptors for fractalkine (CX3CR1) and CCR2 (MCP1) seem to distinguish monocyte subsets that give rise to inflammatory and resident macrophages (see Figure 10-2). Resident macrophages and immature DCs are present in many lymphohematopoietic and nonlymphoid organs; selected markers and properties are also listed in Table 10-1. The CD68 antigen, a late endosome mucin-like glycoprotein related to the lysosome-associated membrane protein (LAMP) family, is the most broadly expressed

**TABLE 10-1** Selected Properties of Mononuclear Phagocytes and Related Cells

| Properties | Functions |
|---|---|
| A. Monocytes<br>Low level in blood (~1%-4%)<br>CD68 dim | |

**TABLE 10-1** Selected Properties of Mononuclear Phagocytes and Related Cells—cont'd

| Properties | Functions |
|---|---|
| B. Macrophages | |
| Widely distributed: lymphohemopoietic tissues as resident and recruited populations | Local and systemic homeostasis<br>Trophic functions—inflammation and repair |
| Variable life span | |
| Heterogeneous phenotype | |
| Sessile (mainly) | |
| Markers $CD68^{++}$, MerTK, CD64, RON | |
| Expressed by mouse resident peritoneal macrophages, CD169 splenic marginal zone metallophils, lymph node subcapsular sinus macrophages | |
| *Endocytosis and phagocytosis:* | Clearance, digestion, host defense |
| Opsonic (Fc, CR) | Humoral immunity |
| Non-opsonic recognition SR (e.g., SR-A, MARCO, lectins, e.g., CD206, Dectin-1) | Defense and homeostasis |
| CD163, CD71, folate receptors | Uptake hemoglobin—haptoglobin, transferrin, B12 |
| Sensing (TLR, cytosolic) | Innate immunity |
| Regulatory receptors (e.g., TREMs, F4/80 [EMR1], mouse, EMR2 [human], GPCR) | Potentiate responses |
| *Biosynthesis and secretion:* | Trophic and cytocidal |
| Pro- and anti-inflammatory cytokines | Inflammation, repair |
| IL-1, TNF, IL-6, IL-12, IL-18, IL-10, TGF-β | Innate immunity |
| Neutral proteinases, enzymes | Tissue injury |
| Low molecular weight mediators: RB, nitric oxide, prostanoids | Defense and inflammation |
| *Modulation:* | |
| Classic (M1) and alternative activation (M2) spectrum | Regulation of cellular immunity |
| *Immune interactions:* | Activation/suppression of primed T cells |
| Expression of class II MHC and co-stimulatory molecules | Adaptive immune regulation |
| C. Dendritic Cells | |
| Minor population in blood, lymph tissues | Sentinel cells |
| Short to medium-lived | Bridge innate to adaptive immunity or tolerance |
| Subsets described, varied antigen markers (e.g., class II MHC, DC-SIGN [CD209], CD11c, CD206/DEC205) | |
| Motile | Migration |
| Chemokine receptors (e.g., CCR7) | Recruitment |
| Transient adhesion | |
| Endocytosis and phagocytosis | Antigen capture |
| *Two-stage maturation/activation:* | Induced by LPS, other ligands (e.g., TLR) |
| Loss endocytosis, macropinocytosis, phagocytosis | Processing, direct and cross-presentation to naïve lymphocytes |
| Intra-cellular class II MHC redistributed to surface | |
| Limited digestion, capture peptides HLA DM | |
| Specialized endosomal compartment (multivesicular bodies, Birbeck granules) | |
| CD1d expression | Lipid antigen presentation |
| Cytosolic sensors | Nucleic acid recognition |
| Co-stimulatory molecules | Activation and inhibition of APC functions |
| TLR, PRR-dependent cytokine production (e.g., IL-12, IL-18) | Activation, regulation of tissue activation |
| D. Plasmacytoid Dendritic Cells | |
| Minor, blood, tissue | |
| Short-lived, labile | |
| Mixed phenotype markers (e.g., CD123 [IL-3R]; TLR3, 7, 9; Siglec H [mouse], RLR, helicases) | |
| *Biosynthesis, secretion:* | |
| Type I $interferon^{+}$ | Anti-viral responses |
| E. Osteoclasts | |
| Multinucleated, CD68, RON, calcitonin receptor | Markers, adhesion, and regulation |
| Tartrate-resistant acid phosphatase, vacuolar $H^{+}$ATPase, proteinase K | Resorption of living bone<br>Polarized secretion |

*Note:* Marker expression varies, depending on cell localization, maturation, and activation. Some markers also are present on other myeloid cells (e.g., polymorphonuclear neutrophils) and on selected endothelial cells. Structures and functions of receptor antigens are described elsewhere in this chapter. For further details see Schraml BU, Reis e Sousa C: Defining dendritic cells. *Curr Opin Immunol* 32:13–20, 2015.

APC, Antigen-presenting cell; ATPase, adenosine triphosphatase; CCR, CC chemokine receptor; CR, complement receptor; DC, dendritic cell; EMR, epidermal growth factor (EGF)-like module containing mucin-like hormone receptor; FcR, Fc receptor; GPR, G-protein-coupled receptor; HLA DM, human leukocyte antigen DM; IL, interleukin; LFA-1, leukocyte function–associated antigen 1; MARCO, macrophage receptor with collagenous structure; MHC, major histocompatibility complex; PRR, pattern recognition receptor; RB, respiratory burst (NADPH oxidase/superoxide, etc.); RLR, Rig-I-like receptor; RON, Recepteur d'Origine Nantais; SR, scavenger receptor; TGF, transforming growth factor; TLR, Toll-like receptor; TNF, tumor necrosis factor; TREM, triggering receptor expressed on myeloid cells.

Modified from Collin M, Hughes A, Plüddemann A, Gordon S: Monocytes, macrophages and dendritic cells. In Greer JP et al, editors: *Wintrobe's clinical haematology*, Philadelphia, 2014, Lippincott Williams and Wilkins.

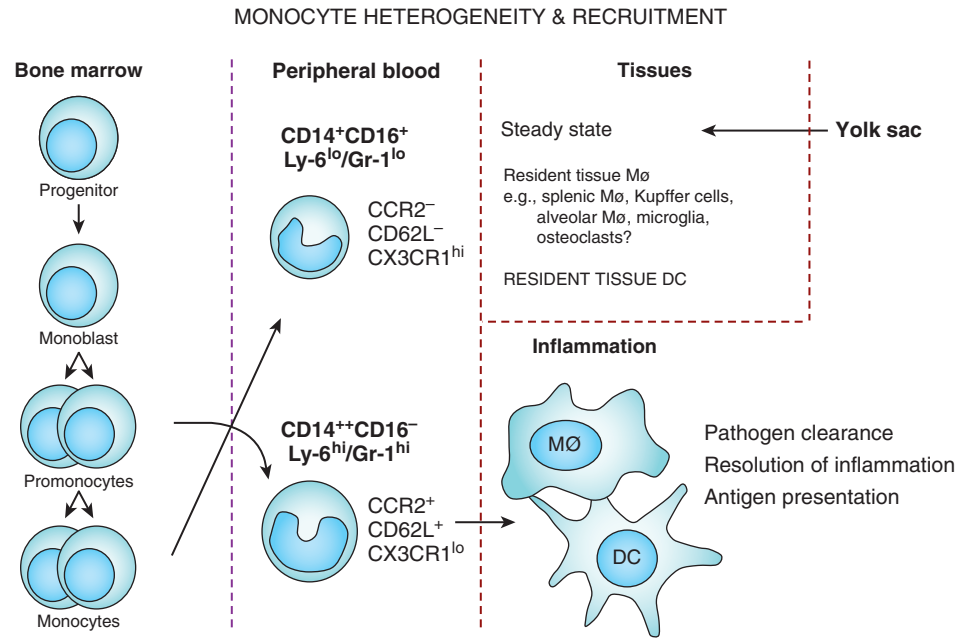

**Figure 10-2** Differentiation and distribution of mononuclear phagocytes. Distinct subpopulations of yolk sac–derived and circulating monocytes are thought to give rise to resident tissue macrophages (MØ), dendritic cells (DCs), and osteoclasts compared with cells recruited by an inflammatory stimulus. Further phenotypic heterogeneity arises from microenvironmental stimuli, such as cytokines and microbial products. *(For additional details see Ginhoux F, Jung S: Monocytes and macrophages: developmental pathways and tissue homeostasis.* Nat Rev Immunol *14:392–404, 2014; Hoeffel G et al: C-Myb(+) erythro-myeloid progenitor-derived fetal monocytes give rise to adult tissue-resident macrophages.* Immunity *42:665–678, 2015; and Lee J, et al: Restricted dendritic cell and monocyte progenitors in human cord blood and bone marrow.* J Exp Med *212:385–399, 2015.)*

marker for all mononuclear phagocytes, although its function is still obscure.

Osteoclasts and resident macrophages are found on the surface of bone and display distinct phenotypes. Although antigenic markers for human and mouse mononuclear phagocytes are useful for phenotypic analysis, no single marker is definitive in their classification, and it is impossible, in most tissues, to distinguish locally activated resident cells from "elicited," newly recruited, and locally activated monocytes. This problem is due in part to rapid modulation of antigen expression in blood monocytes when they enter a particular tissue microenvironment. Species differences in anatomy and in marker expression are a further confounding factor.

Apart from the expression of chemokine receptors,[35] adhesion molecules play a role in selective monocyte "homing," but their differential expression by macrophages, DCs, and osteoclasts is less well defined than for lymphocyte subpopulations. Adhesion molecules include various heterodimeric integrins implicated in adhesion to endothelium, to extra-cellular matrix, and to bone. There is considerable scope for characterization of additional receptors and markers; one example is the EGF-TM7 family of leukocyte receptors, illustrated in Figure 10-3.[36] Although the F4/80 antigen has been extremely useful as a differentiation marker in the mouse, the human counterpart (EMR1) has not been of comparable value, showing a predilection for eosinophils. EMR2, a related human myeloid cell receptor, is a useful marker, although it is expressed by many tissue mononuclear phagocytes, as well as other myeloid leukocytes; it binds chondroitin sulfate proteoglycans that are broadly present in connective tissue and has been implicated in leukocyte adhesion, migration, and activation.[37]

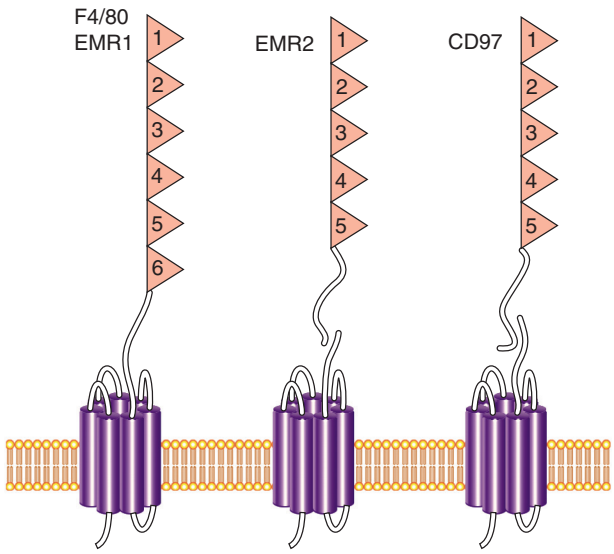

**Figure 10-3** Myeloid cell antigens of the EGF-TM7 family. These G protein–coupled receptor (GPCR)-related receptors have a large extracellular domain consisting of multiple epidermal growth factor (EGF) modules. The F4/80 antigen, an excellent marker for mouse macrophages, has been implicated in peripheral tolerance.[110] The human orthologue EGF-like module containing mucin-like hormone receptor (EMR)1 is a marker for human eosinophils. EMR2 is not expressed in the mouse but is present on human monocytes, macrophages, immature myeloid dendritic cells, and activated polymorphonuclear neutrophils. It is a useful surface marker for macrophages in tissues, including rheumatoid arthritic joints. CD97, expressed on myeloid cells and selected non-myeloid cells, is a receptor for the complement regulatory protein, CD55.[111] EMR2 and CD97 bind chondroitin sulfate B.[37]

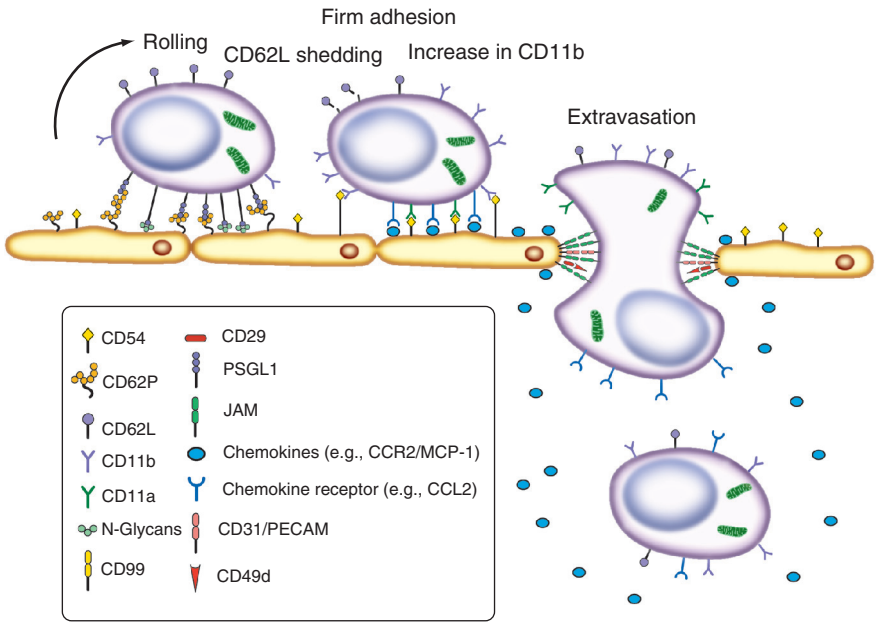

**Figure 10-4** Stages and molecular interactions implicated in monocyte recruitment by inflammatory stimuli. Diapedesis of monocytes shares features with polymorphonuclear neutrophils.

In joints, a resident synovial macrophage population is present, and recruited monocytes and macrophages are prominent in inflammatory, autoimmune, and infectious diseases, together with DCs and other myeloid and lymphoid cells. These resident and recruited mononuclear phagocytes have not yet been attributed to particular monocyte subsets. These may not be the same monocyte subpopulations that give rise to resident and recruited mononuclear phagocytes in other tissues and in response to different diseases.

## MOBILIZATION OF MONONUCLEAR PHAGOCYTES

Similar to other white blood cells, mononuclear phagocytes are distributed in intravascular and extravascular compartments, sharing common mechanisms of mobilization but also displaying distinct features among themselves and compared with other cell types. Exit from the bone marrow is controlled constitutively and on demand, but this process is not well understood, except for the role of chemokine receptors, such as CCR2 (ligands MCP1 through MCP4).[38] It is not known what determines differentiation into the mature macrophages that form part of the stromal microenvironment in bone marrow; one possibility is re-entry of circulating monocytes from blood to bone, as for osteoclasts. Apart from the circulating pool of monocytes, many mature macrophages adopt a sinusoidal distribution in liver (Kupffer cells) and in selected lymphoid and endocrine organs.[39] These cells are distinct from, but share endocytic properties with, sinusoidal endothelial cells. The constitutive exit through vascular endothelium to become tissue macrophages and DCs is not understood, whereas induced mobilization is well characterized, sharing many features with polymorphonuclear neutrophils.

Figure 10-4 summarizes stages and molecules implicated in monocyte egress. Although most monocytes exit the microvasculature by diapedesis between endothelial cells, evidence of an alternative transcytotic mechanism is present, as for lymphocytes. The roles of L-selectin, β2 and other integrins, the immunoglobulin superfamily molecule CD31, and CD99 have been established by analysis of genetic deficiencies in humans and mice[40] and by the use of monoclonal antibodies against these[41] and other defined adhesion molecules, such as vascular cell adhesion molecule-1 (VCAM-1) and very late activation antigen-4 (VLA-4). Endothelial cell ligands implicated in monocyte adhesion include fractalkine, a tethered chemokine; other chemokines may be presented by glycosaminoglycans.

The subsequent migration and fate of mononuclear phagocytes in tissues differ strikingly. Although many resident macrophage and DC subpopulations in tissues are well characterized,[8,42] the origins of several functionally specialized cell types related to this overall lineage remain unclear.[43] Macrophages become sessile but can be induced by inflammatory stimuli to migrate to draining lymph nodes and remain there, without re-entering the circulation. Immature DCs respond to antigenic and inflammatory stimuli by migrating to draining lymphoid tissues, thereby transporting antigens for presentation to lymphocytes. The subcapsular sinus macrophages of lymph nodes have been implicated in trapping of DC antigen transported by afferent lymph[44] (Figure 10-5). DC maturation is accompanied by major changes in DC properties (Figure 10-6 and Table 10-2). DCs become highly motile and express a range of chemokine and adhesion receptors. Entry of myeloid DCs and tissue macrophages into lymphatics is less well understood but may involve interactions with the mannose receptor. As a result, DCs can present exogenous antigens and self-antigens to CD4 T lymphocytes to activate or tolerize their responses.

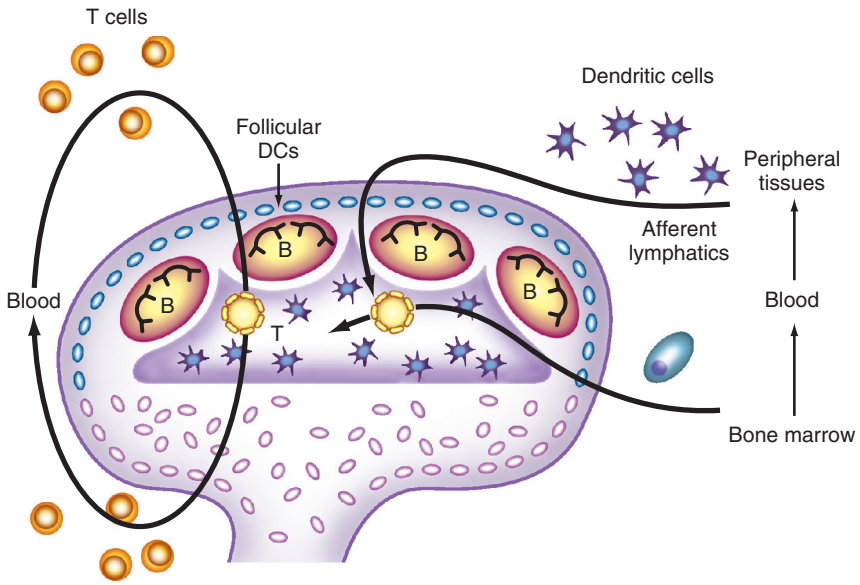

**Figure 10-5** Positioning of dendritic cells (DCs) within lymphoid tissues. Yolk sac–derived precursors enter skin and mucosal peripheral tissues and differentiate into Langerhans cells within epithelia and into other immature DCs. When established, Langerhans cells turn over independently from bone marrow–derived cells[50] (e.g., after ultraviolet irradiation). Upon exposure to stimuli (e.g., foreign antigens and local infections) and constitutively (after uptake of apoptotic cells, such as in the gastrointestinal tract), DCs undergo maturation, upregulate CCR7, and enter afferent lymphatics and secondary lymphoid tissues, where they interact with CD4 T lymphocytes. CD4 T lymphocytes become activated, interacting with B cells or CD8 T lymphocytes, and re-enter blood, homing to peripheral sites. DCs also are able to interact with innate lymphocytes and natural killer cells. Follicular DCs in B cell areas have a distinct, poorly defined bone marrow origin, express novel antigenic markers, and are able to capture immune complexes through complement activation. Plasmacytoid DCs have a distinct interfollicular location and express markers of a myeloid and a lymphoid nature. Subcapsular macrophages resemble splenic marginal metallophilic macrophages and contribute to antigen capture. *(Courtesy R. Steinman.)*

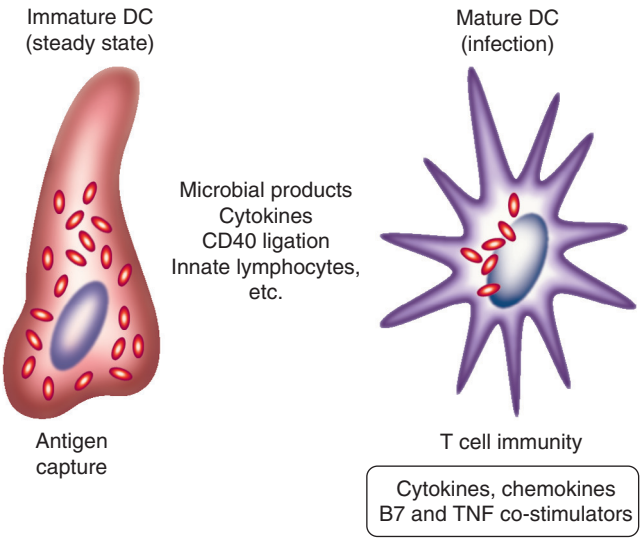

**Figure 10-6** Dendritic cell (DC) maturation. In the steady state, immature DCs are actively endocytic, capturing antigens efficiently through pattern recognition receptors. In response to a range of exogenous and endogenous stimuli, they translocate major histocompatibility complex class II to the surface, express a range of co-stimulatory molecules and secretory products, and become efficient antigen-presenting cells. As a result, DCs control adaptive immunity or induce tolerance. TNF, Tumor necrosis factor. *(Courtesy R. Steinman.)*

**TABLE 10-2** Maturation Markers for Human Monocyte–Derived Dendritic Cells

| | Immature | Mature |
|---|---|---|
| **Enhancer/Co-Stimulatory Molecules** | | |
| CD80 (B7-1) | Low | High |
| CD86 (B7-2) | Low | High |
| CD83 | | De novo |
| EMR2 (CD312) | High | Moderate/low |
| **Antigen Uptake** | | |
| FcγRII | High | Low |
| **Signaling** | | |
| CD40 | Low | High |
| CXCR4 | Low | High |
| CCR5 | High | Low |
| CCR6 | High | Low |
| CCR7 | Low | High |
| **Antigen Presentation** | | |
| HLA-DR (class II) | Moderate | High |
| HLA-DQ (class II MHC) | Moderate | High |
| CD1a | High | Low |
| **Others** | | |
| DC-SIGN (CD209) | High | Low |
| CD14 | High/moderate | Negative |
| CD123 (IL-3R) | Low | High |

*Note:* In addition to the listed antigens and antigen-presenting cell functions, dendritic cell production of and response to other growth factors, chemokines and cytokines, microbial products, and immune complexes varies during maturation and activation in vitro. Validation in vivo is incomplete.

DC-SIGN, Dendritic cell–specific intra-cellular adhesion molecule 3 (ICAM-3)-grabbing nonintegrin; EMR2, epidermal growth factor (EGF)-like module-containing mucin-like hormone receptor-like 2; HLA, human leukocyte antigen; IL, interleukin; MHC, major histocompatibility complex.

Although in vitro systems are widely used to generate DCs by cultivation of monocytes or bone marrow precursors in cytokine-supplemented media (GM-CSF, with or without IL-4), their properties may not correspond to those of DC populations in vivo.

Mononuclear phagocytes use integrins and receptors for extra-cellular matrix such as CD44, thus regulating the dynamics of their adhesion and migration. Osteoclast adhesion to bone depends on αvβ3 and possibly other adhesion molecules implicated in podosome attachment. Plasma membrane receptors such as CD97 and EMR2, members of the EGF-TM7 family, and triggering receptor expressed on myeloid cells (TREM)-1,[45] an immunoglobulin superfamily molecule with an immunotyrosine-based activation motif (ITAM) (see later discussion), regulate myeloid cell effector functions and adhesion and migration within extravascular tissue compartments.

Monocytes recruited to tissues by poorly degradable foreign materials or by selected microbial pathogens or parasites form granulomas, that is, organized structures rich in macrophages, incorporating other myeloid and lymphoid cells, fibroblasts, and extra-cellular matrix. Pathogen-induced granuloma formation[46] depends on adhesion molecules such as CR3, a β2 integrin, TNF, and chemokine receptors such as CCR4; granuloma macrophages express abundant secretory products such as lysozyme[47] and pro-inflammatory cytokines. Characteristic morphologic evidence of macrophage differentiation in granulomas includes epithelioid cell and multinucleated giant cell formation, such as with *Mycobacterium tuberculosis* infection. Giant cells arise by monocyte recruitment and macrophage fusion, rather than by impaired cytokinesis.[48,49] Cytokines such as IL-4 and IL-13, acting through a common receptor chain, and GM-CSF promote macrophage fusion. Foreign surfaces including biomaterials also can play a role in granuloma formation, and chemokine receptors have been implicated in the induction of foreign body–induced giant cells.

The surface molecules involved in these examples of macrophage homokaryon formation and the functional significance of induced fusion are still poorly understood. By contrast, multinucleation in osteoclasts is a physiologic process, dependent on M-CSF and RANK ligand, and several plasma membrane (CD44, CD9, TREM-2, and DC-STAMP) and intra-cellular (c-src and c-fos) molecules have been implicated in this differentiation process. Multinucleation is thought to favor efficient localized resorption of bone. Osteoclasts become polarized for secretion and display highly active plasma membrane ruffling. Interactions with osteoblasts; local cytokines, such as osteoprotegerin; and circulating hormones, including calcitonin, parathormone, and vitamin D metabolites, regulate their gene expression and function, as is discussed in Chapter 4. Vitamin D receptors also modulate the function of macrophages and DCs.

The turnover of different mononuclear phagocytes varies, depending on their activation status and tissue localization.[50] Resident macrophages can live for weeks or months, whereas inflammation reduces survival to hours or days. DCs are relatively short-lived cells; osteoclast turnover in vivo has not been studied in detail. The role of apoptosis in mononuclear phagocyte turnover is poorly characterized, in contrast to that in polymorphonuclear neutrophils, but cell survival is regulated by growth factors such as M-CSF and by interactions with neighboring cells and pathogens.

## RECOGNITION

In the past decade, emphasis on the problem of immune recognition has shifted to a considerable extent from somatically rearranged receptors for peptide on lymphocytes to germline-encoded receptors on myeloid antigen-presenting cells (APCs).[51-54] Previous studies on myeloid cells focused on well-known opsonic receptors for antibody (Fc receptors [FcRs]) and complement (complement receptor). The concept of direct pattern recognition receptors for conserved structures on microbes provided an impetus to studies on innate immunity, reinforced by the discovery of TLRs. More recently, investigation of numerous NTRs, including a range of lectin-like recognition molecules and of scavenger receptors (SRs), markedly enhanced knowledge of the recognition repertoire.[18] Finally came the discovery of cytosolic recognition proteins, the NLR, retinoic acid inducible gene (RIG)-I families, and AIM2,[55] which are implicated in genetic and microbially induced hyperinflammatory syndromes, Crohn's disease, and nucleic acid sensing.

These molecules are mainly, although not exclusively, expressed by macrophages and DCs and play an important role in immune responses to foreign or modified host ligands, resulting in inflammation and autoimmunity. Given the complexity of microbial and cellular particulates compared with discrete soluble ligands, different receptors collaborate and synergize with one another to activate or inhibit subsequent APC responses. The original distinction drawn between pattern recognition receptors for exogenous, so-called pathogen-associated molecular patterns and for endogenous, host-derived ligands has been eroded to some extent because individual receptors are able to bind both types of ligand,[56] although their distinct cellular expression and signaling responses may account for discrimination by host APCs. In particular, recognition and uptake of apoptotic cells result in downregulation of macrophage effector molecules, as opposed to the pro-inflammatory effects induced by microbial ligands. The signaling pathways induced by other, modified host-derived ligands, such as oxidized lipoproteins and hyaluronates, are not well characterized.

This section summarizes selected receptor structures, indicates some of their ligands, and addresses briefly signaling and antigen-processing pathways. Further details are provided in Chapter 17, which also illustrates interactions between humoral and cellular arms of the innate response.

### Toll-Like Receptors

Key features of TLRs are illustrated elsewhere (see Chapter 17).[57,58] TLRs consist of homodimers or heterodimers of transmembrane glycoproteins containing extra-cellular leucine-rich repeats (LRRs) and cytoplasmic Toll/IL-1 receptor (TIR) domains, similar to the intra-cellular domain of the IL-1 receptor, which contains extra-cellular immunoglobulin superfamily domains. TLRs are expressed on the surface of APCs or, in the case of TLR3, TLR7/8, and TLR9, on vacuolar membranes, contributing to pro-inflammatory

and immunogenic signaling after "sensing" of cargo. Isolated TLRs do not bind ligands directly but collaborate with humoral factors and with other plasma membrane glycoproteins, as in the well-studied case of TLR4, the glycosyl phosphoinositide (GPI)-anchored CD14 receptor for the plasma LPS-binding protein and the membrane-associated molecule MD2.

## Non–Toll-Like Receptors

NTRs constitute a variety of lectin-like,[53,59] scavenger, and other plasma membrane glycoprotein non-opsonic receptors; selected examples are illustrated in Figures 10-7 and 10-8. They include type 1 and 2 transmembrane molecules, with C-type lectin or lectin-like, collagenous, or immunoglobulin superfamily domains. In addition, macrophages express sialic acid–binding receptors, which are members of the SIGLEC family,[60] as do plasmacytoid dendritic cells (pDC). Table 10-3 summarizes known ligands and potential functions relevant to their role in homeostasis and immunity. Apart from direct recognition of selected self, modified self, and foreign structures, they play an important role in cell-cell and cell-matrix interactions; in phagocytosis and endocytosis; and in less well-understood processes, such as targeted delivery of antigens to peripheral lymphoid organs.[61]

Receptors that promote rapid clearance of apoptotic cells, directly or after opsonization by complement and other extra-cellular proteins, are shown in Figures 10-9 and 10-10. More recent research has shown collaboration of different receptors at the cell surface,[62] regulating cellular responses. Other regulatory surface receptors include transmembrane molecules with tyrosine-based activating (ITAM) or inhibitory (ITIM) cytoplasmic motifs—for example, C-type lectin-like molecules, immunoglobulin superfamily members such as FcRs, discussed further subsequently, and receptor-ligand pairs that regulate macrophage activation (CD200/CD200R)[63] and phagocytosis (SIRPα and CD47; Figure 10-11).[64]

## Complement Receptors

Complement receptors are heterogeneous receptors expressed by APCs (Figure 10-12) that mediate direct and lectin- and antibody-dependent binding of activated complement components and play a role in cell migration and phagocytosis and immune regulation.[65] The discovery of a novel complement receptor selectively expressed by Kupffer cells suggests that mononuclear phagocyte heterogeneity in complement receptor function provides evidence of tissue specificity for some macrophage subsets.[66] Genetic deficiencies in complement receptor expression and their ligands have provided insights into the pathogenesis of autoimmune disease and of rheumatic joint injury.[67] Complement deposition on follicular DCs has been implicated in the activation of B cell responses. Complement regulatory proteins are expressed by many cell types and by APCs and play an important role in limiting cell activation. In addition, complement receptors collaborate with other receptors to modulate myeloid cell responses. Their signaling pathways are less well defined than those of FcRs.

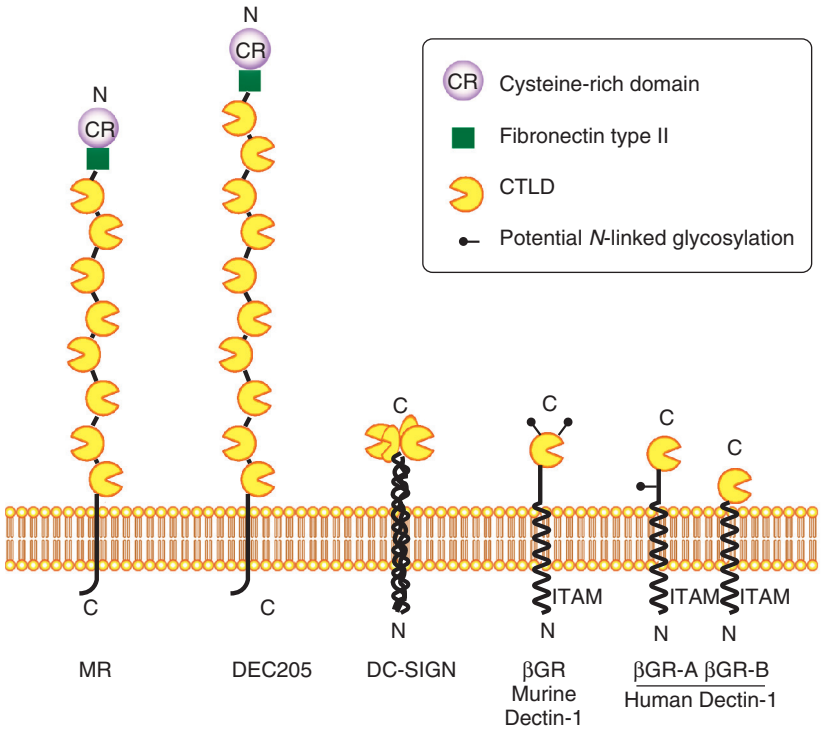

**Figure 10-7** Selected lectin-like receptors expressed by macrophages and dendritic cells (DCs; see Table 10-3 for ligands). These receptors play an important role in non-opsonic adhesion, cell-cell interactions, endocytosis, and phagocytosis. The cysteine-rich (CR) domain of the mannose receptor (MR)[53,54] has been postulated to play a role in transport of glycoconjugates to peripheral lymphoid organs for clearance or antigen-dependent activation of B lymphocytes.[61] DEC205 has been used to show efficient targeting of antigens to DCs.[112] The immunoreceptor tyrosine-based activation motif (ITAM)-like motif of Dectin-1, the β-glucan receptor (βGR), is essential for myeloid cell and Th17 lymphoid responses to fungal particles, in collaboration with Toll-like receptor[59,62,91,113] and nucleotide oligomerization domain (NOD)-like receptor. CTLD, C-type lectin domain.

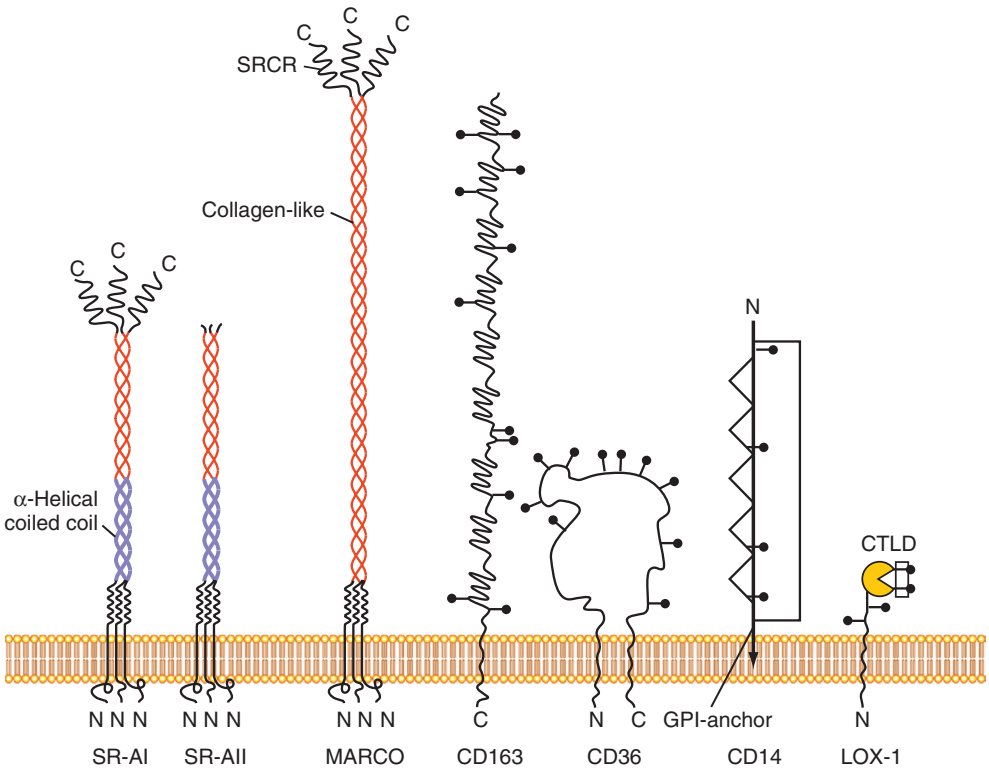

**Figure 10-8** Selected scavenger receptors. These non–Toll-like receptors (NTLRs) consist of diverse structures and bind a range of microbial and endogenous ligands (see Table 10-3).[114,115] They differ in regulation and expression, providing useful markers of macrophage activation (CD14, macrophage receptor with collagenous structure [MARCO]),[15,115,116] heterogeneity (CD163, the scavenger receptor [SR] for clearance of haptoglobin-hemoglobin complexes),[98] and lipid homeostasis (SR-A, CD36, and lectin-like oxidized LDL receptor-1 [LOX-1]).[114] Scavenger receptors such as MARCO can collaborate with TLRs in antigen-presenting cell responses to microbes.[117] CTLD, C-type lectin domain; GPI, glycosyl phosphoinositide; SRCR, scavenger receptor cysteine-rich.

**TABLE 10-3** Ligands for Selected Non-Opsonic, Non–Toll-like Receptors

| Class | Receptor | Microbial Ligands | Endogenous Ligands | Function |
|---|---|---|---|---|
| Scavenger receptors | SR-A I/II | Gram-positive/gram-negative bacteria | Apoptotic cells | Phagocytosis |
| | | Lipoteichoic acid<br>Lipid A<br>Neisserial surface proteins | Modified low-density lipoproteins<br>AGE-modified proteins<br>β-Amyloid | Endocytosis<br>Adhesion<br>Foam cell formation |
| | MARCO | Gram-positive/gram-negative bacteria<br>Neisserial surface proteins | Marginal zone B lymphocytes<br>Uteroglobin-related protein | Adhesion<br>Phagocytosis<br>Innate activation |
| | CD36 | Deacylated lipopeptide from gram-positive bacteria | Apoptotic cells (with thrombospondin and vitronectin receptor) | Uptake, exchange of lipids, macrophage fusion |
| | | *Plasmodium falciparum*–parasitized erythrocytes | HDL<br>Outer rod segments | Adhesion |
| Lectins | Dectin-1 | β-Glucan | T lymphocytes (noncarbohydrate) | Fungal uptake and immunomodulation |
| | DC-SIGN | Mannosyl/fucosyl glycoconjugates including viruses (e.g., human immunodeficiency virus-1) | ICAM 2/3 T lymphocytes | Adhesion<br>Endocytosis |
| | Mannose receptor CRD | Mannosyl/fucosyl glycoconjugates on bacteria, viruses (e.g., dengue), fungi, parasites | Lysosomal hydrolases<br>Thyroglobulin<br>Ribonuclease<br>β-Amylase | Adhesion<br>Endocytosis |
| | Cysteine-rich domain | | Sulfated carbohydrates in marginal zone (spleen) and subcapsular sinus (lymph node) | Antigen targeting |
| | Fibronectin type II domain | | Collagens | Adhesion |

*Note:* This table illustrates the dual recognition properties and diverse cellular functions of selected non–Toll-like receptors. For additional details, see references 53, 115, and 122-125.

AGE, Advanced glycation end product; CRD, carbohydrate recognition domains ($Ca^{++}$-dependent); DC-SIGN, dendritic cell–specific intra-cellular adhesion molecule 3 (ICAM-3)-grabbing nonintegrin; HDL, high-density lipoprotein; ICAM, intercellular adhesion molecule; MARCO, macrophage receptor with collagenous structure.

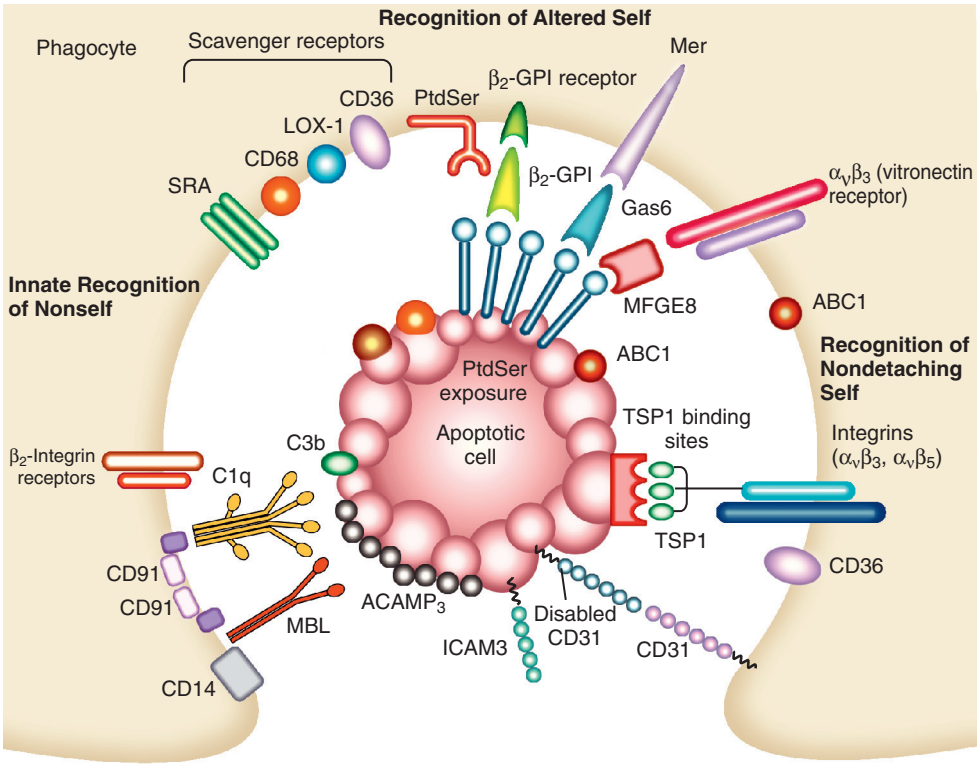

**Figure 10-9** Phagocytic receptors for apoptotic cell phagocytosis.[118] Macrophages (MØ) and immature myeloid dendritic cells (DCs) are the main immune cells involved in the clearance of apoptotic cells. They express broadly similar multiple receptors, which can bind directly or via opsonic soluble proteins (e.g., mannose-binding lectins [MBLs] to ligands). Phosphatidylserine (PtdSer) becomes exposed on the outer surface of the apoptotic cell, and a receptor for this ligand has been long sought. A new receptor (T cell immunoglobulin mucin (TIM)4 and related TIM1) has been discovered on resident MØ, with specificity for PtdSer. Other MØ populations use MFGE8 (a milk fat globulin protein secreted by MØ) as an opsonin. Discrimination of non-self and altered self may involve combinations of different phagocyte receptors. Apoptotic cell uptake results in an anti-inflammatory response by MØ (e.g., release of transforming growth factor-β and prostaglandin $E_2$) and has been implicated in cross-presentation by DCs. ABC1, Adenosine triphosphate-binding cassette 1; $ACAMP_3$, apoptotic cell–associated molecular pattern 3; GPI, glycosyl phosphoinositide; ICAM3, intercellular adhesion molecule-3; LOX-1, lectin-like oxidized LDL receptor-1; MFGE8, milk fat globule–epidermal growth factor 8 protein; SRA, scavenger receptor A; TSP1, thrombospondin 1. *(From Savill J, Dransfield I, Gregory C, et al: A blast from the past: clearance of apoptotic cells regulates immune responses.* Nat Rev Immunol *2:965–975, 2002.)*

## Fc Receptors

APCs express diverse receptors for monomeric and complexed immunoglobulins that regulate effector responses to antigens. Figure 10-13 illustrates the properties of human FcRs with activating or inhibitory motifs in their cytoplasmic tails. FcR polymorphisms have been implicated in autoimmune human diseases such as systemic lupus erythematosus (SLE). Studies on genetically manipulated mouse models have led to considerable insights into the role of individual FcRs in immunopathogenesis. FcRs are able to cooperate with chemokine and other receptors. The nature and role of Fc-dependent and Fc-independent interactions of antibody with APCs are under investigation and include lectin-like recognition of sialylated[68] and mannosyl[69] residues.

## Cytosolic Receptors

Identification of microbial peptidoglycan breakdown and other products as ligands for an intra-cellular family of leucine-rich repeat (LRR)-containing cytosolic sensors that regulate caspase activation and IL-1β secretion, especially in macrophages, provided a major impetus to this burgeoning field.[2,18] Other chapters describe examples of NLRs and their role in hyperinflammatory syndromes, as well as RIG-I–like and other nucleic acid sensing receptors. NLRs and other cytosolic receptors participate in signaling pathways implicated in TLR-induced functions and play a major role in inflammasome activation, caspase-1 activation, and IL-1 and IL-18 release.

RIG-I and melanoma differentiation–associated protein 5 (MDA-5) are members of the RIG-I–like receptor (RLR) RNA helicase family, which are found in macrophages and other myeloid cells, as well as in nonhematopoietic cells. They play a role in recognition of viral RNA, such as single-stranded RNA with 5′-triphosphate and/or double-stranded RNA (see later discussion). Although distinct, they share signaling features (e.g., recruitment by adapter IFN-β promoter stimulator 1 [IPS; also known as *MAVS*, *CARDIF*, or *VISA*] to the outer membrane of mitochondria) and activate transcription factors involved in type I IFN induction and anti-viral immunity. RLR recognition of RNA is predominant in macrophages, conventional (c)DCs, and fibroblasts, but plasmacytoid (p)DCs utilize TLR preferentially.[70] Gene deletion[71] or silencing has shown that RIG-I modulates the generation and differentiation of granulocytes in the absence of virus infection and that it is involved in

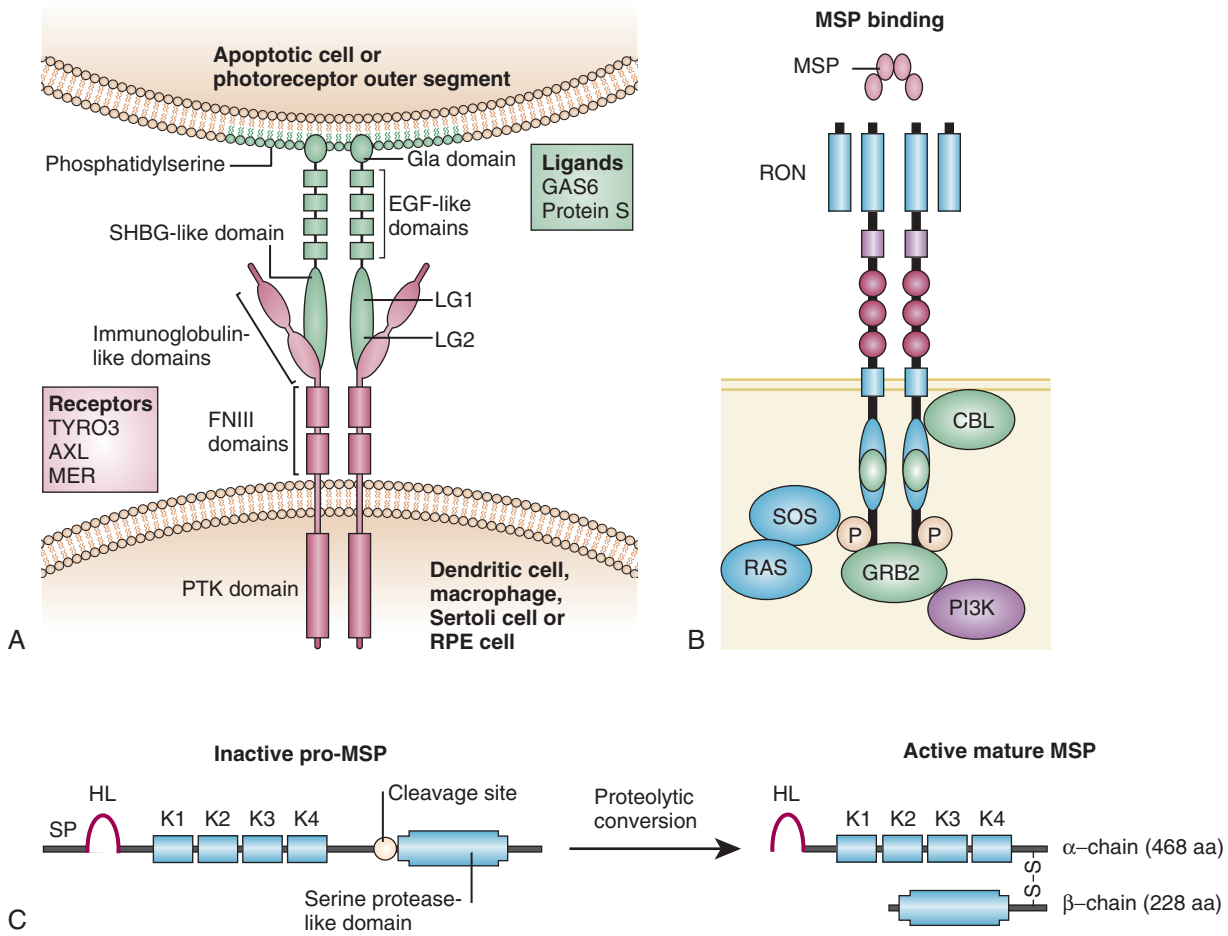

**Figure 10-10** Receptor protein tyrosine kinases expressed by mononuclear phagocytes. **A,** TYRO3, AXL, and MER are receptor protein tyrosine kinases (PTKs) that are expressed by dendritic cells (DCs), macrophages, and immature natural killer (NK) cells of the immune system, Sertoli cells of the testis, retinal pigment epithelial (RPE) cells of the eye, and several other cell types. TAM receptor dimers bind to their two ligands, growth-arrest–specific 6 (GAS6) and protein S, through interaction between the two N-terminal immunoglobulin-like domains of the receptors and the two C-terminal laminin G (LG) regions, which together make up the sex hormone binding globulin (SHBG) domain, of the ligands. (The solved x-ray crystal structure of the GAS6 SHBG domain bound to the immunoglobulin domains of AXL7 reveals that both ligand and receptor crystallize as dimers.) Via their N-terminal Gla domains, GAS6 and protein S then bind to phosphatidylserine that is displayed on the extra-cellular surface of the plasma membranes of apoptotic cells or on the outer segments of photoreceptors. **B,** Macrophage-stimulating protein (MSP)-induced Recepteur d'Origine Nantais (RON) dimerization is the classical mode of activation. RON is selectively expressed by resident peritoneal mouse macrophages and osteoclasts. **C,** Pro-MSP is cleaved at Arg554–Val555 to form a 50 kDa α chain and a 30 kDa β chain linked by a disulphide bond. The α chain contains a hairpin loop (HL) followed by four kringle domains (K1–K4). The β chain has a serine protease-like domain harboring a high-affinity binding site for RON4. CBL, Casitas B-lineage lymphoma E3 ubiquitin-protein ligase; EGF, epidermal growth factor; FNIII, fibronectin type III; GRB2, growth factor receptor-bound protein 2; PI3K, phosphatidylinositol 3-kinase; RAS, small GTPase encoded by ras gene; SOS, son of sevenless; SP, transcription factor binding site SP-1. (***A,*** *From Lemke G, Rothlin CV: Immunobiology of the TAM receptors.* Nat Rev Immunol *8:327–336, 2008.* ***C,*** *From Yao HP, Zhou YQ, Zhang R, Wang MH: MSP-RON signalling in cancer: pathogenesis and therapeutic potential.* Nat Rev Cancer *13:466–481, 2013.)*

phagocytosis of bacteria by LPS-stimulated macrophages, indicating broad function in innate immunity.[72]

AIM2 is a DNA-sensing cytosolic protein that triggers the NACHT domain, LRR domain, and pyrin domain (PYD)-containing protein (NALP)-independent inflammasome.[55] It contains an N-terminal pyrin domain and a C-terminal oligonucleotide binding domain. It binds double-stranded DNA, recruits the inflammasome adaptor protein apoptosis-associated speck-like protein containing CARD (ASC), and becomes localized to ASC-containing speckles, forming a pyroptosome and inducing pyroptotic cell death mediated by caspase-1. RNA silencing impairs DNA-induced maturation of IL-1β in THP-1 human monocytic cells, abrogating caspase-1 activation by double-stranded DNA or *Vaccinia* infection. PYHIN proteins AIM2 and IFI16 form a new family of innate DNA sensors, termed *AIM2-like receptors* (ALRs).[73]

## Damage/Danger-Associated Molecular Patterns

Host-derived molecules that activate TLR pathways and inflammasomes such as NLRP3 include nuclear and cytosolic proteins (e.g., HMGB1 and S-100), matrix components (hyaluronate), adenosine triphosphate (ATP), and uric acid. They are released by cell stress, especially necrosis, and contribute to the initiation and perpetuation of sterile and infectious inflammation. Other receptors include receptor for advanced glycation end products (RAGE) and possibly scavenger receptors, although ligands are promiscuous

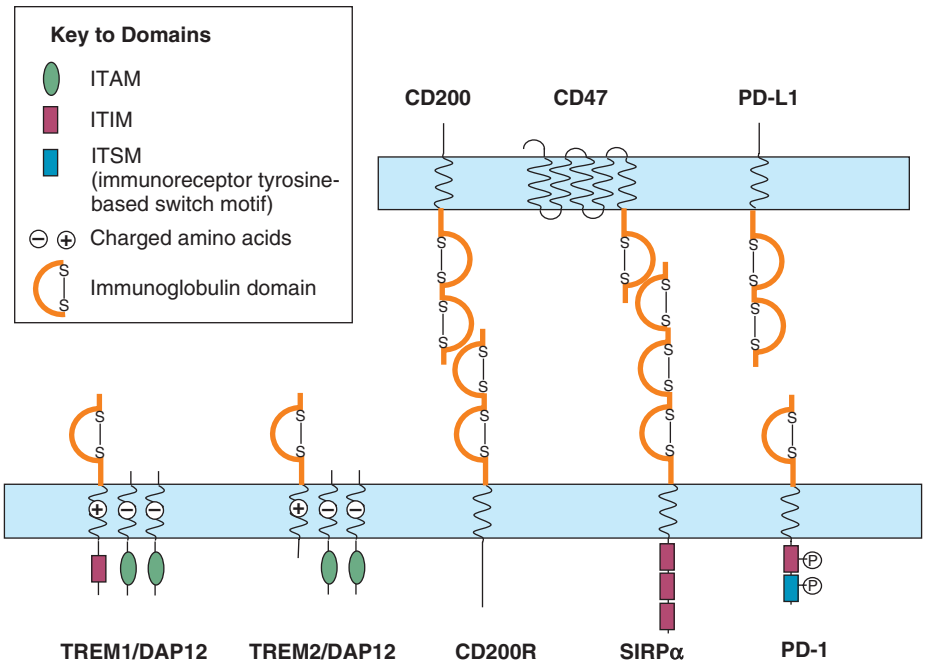

**Figure 10-11** Surface receptors that, singly or as paired receptors, modulate macrophage responses. Illustrated are immunoglobulin superfamily and associated transmembrane molecules using immunoreceptor tyrosine-based activation motifs (ITAMs) or immunoreceptor tyrosine-based inhibitory motifs (ITIMs) to generate activating or inhibitory signals. DAP12 can associate with a range of other membrane molecules as a signaling partner in macrophages, dendritic cells, and natural killer cells.[119] Note the charged amino acid residues in transmembrane domains. CD200 and CD47, which are broadly expressed in tissues, generate inhibitory signals in macrophages via CD200R[63] and signal regulatory protein α (SIRPα).[55] In CD200 knockout mice, macrophages show spontaneous activation.[109] Macrophages themselves are induced by Toll-like receptor stimuli to express CD200.[63] The extracellular region of programmed cell death 1 (PD-1) consists of a single immunoglobulin (Ig)V-like domain, and its cytoplasmic region contains an ITIM and an immunoreceptor tyrosine-based switch motif (ITSM). The expression of PD-1 can be induced not only in T cells but also in B cells and myeloid cells, suggesting PD-1 has broader roles in immune regulation. PD-L1 is a type I transmembrane protein with IgV- and IgC-like domains in the extracellular region. PD-L1 is constitutively expressed in T cells, B cells, macrophages, and dendritic cells and further upregulated after activation of these cells. TREM, Triggering receptor expressed on myeloid cells. *(From Okazaki T, Honjo T: The PD-1-PD-L pathway in immunological tolerance.* Trends Immunol *27:195–201, 2006).*

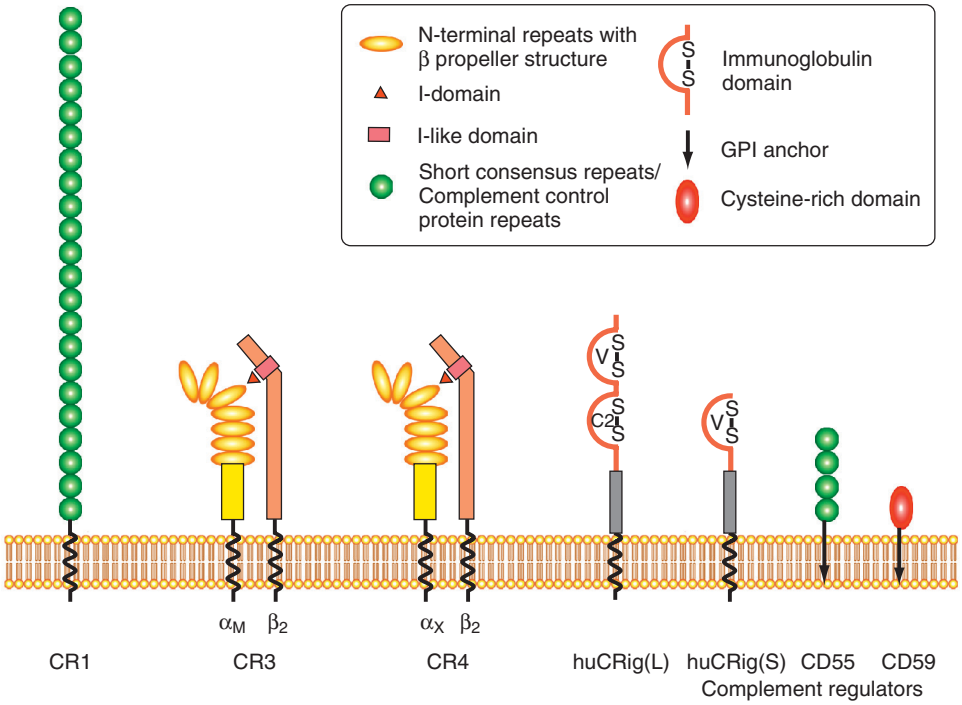

**Figure 10-12** Complement receptors and membrane regulators expressed by macrophages. CR1 is broadly expressed by nucleated cells, acting as a "sink" for activated complement; CR3 (CD11b/CD18), a phagocytic receptor for C3b-coated particles, and CR4 (CD11c/CD18) are β2 integrins, which, together with leukocyte function–associated antigen 1 (LFA-1) (CD11a/CD18), mediate adhesion of myeloid cells to endothelium and extra-cellular matrix and migration. huCRIg L and S are long and short forms of a complement-binding receptor on Kupffer cells, which mediate uptake of opsonized bacteria.[66] CD55 and CD59 are glycosyl phosphoinositide (GPI)-anchored regulators of complement activation.

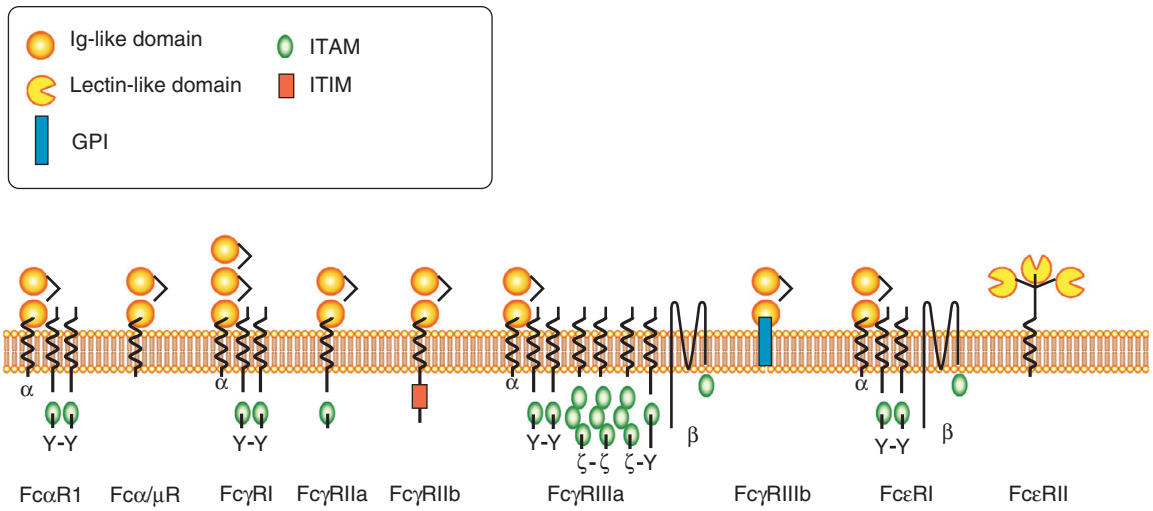

**Figure 10-13** Human Fc receptors. Myeloid cells express a range of classic Fc receptors that initiate a variety of cellular responses, including phagocytosis, antibody-dependent cell-mediated toxicity, antigen presentation, respiratory burst, and release of inflammatory mediators. Immunoglobulin subclasses are bound by extra-cellular domains; signaling via cytoplasmic immunotyrosine activation motif (ITAM) or immunotyrosine inhibition motif (ITIM) is mediated by associated membrane-spanning polypeptides. Activation and inhibitory receptors usually are co-expressed on the cell surface and function in concert, determining the magnitude of effector cell responses. A range of Fc receptor–like molecules (immunoglobulin superfamily [IGSF] extra-cellular domains) with similar ITAM/ITIM cytoplasmic motifs are mainly expressed by B or T/natural killer cells; they may regulate lymphocytic differentiation and responses.[120] GPI, Glycosyl phosphoinositide.

and often are poorly defined. The concept gained currency from work by Matzinger and colleagues.[74] Various hypotheses have been proposed for inflammasome activation, including $K^+$ efflux, membrane pore formation, lysosome disruption and cathepsin release, and reactive oxygen species (ROS), which may be necessary but is not sufficient for caspase activation (Figure 10-14).[75]

Figures 10-15 and 10-16 summarize features of intracellular nucleic acid recognition and signaling, including a model for cyclic guanosine monophosphate (GMP)-adenosine monophosphate (AMP) synthase (cGAS)-mediated cytosolic DNA sensing.

## RESPONSES AND MODULATION

This section summarizes some of the major cell biologic effects resulting in antigen processing and presentation by APCs. Other chapters address related topics, such as recognition of lipids by CD1 and intra-cellular trafficking of related molecules.

### Phagocytosis and Endocytosis: Antigen Processing

The vacuolar apparatus of APCs is illustrated schematically in Figure 10-17.[76,77] Internalization of the plasma membrane results in phagosome/endosome formation, with progressive acidification and digestion, depending on delivery of vesicles and their hydrolytic contents. Membrane and receptors are recruited, modified by maturation, and retrieved by recycling. Further fusion with Golgi-derived vesicles and primary lysosomes yields phagolysosomes and secondary lysosomes, reaching a pH of approximately 5.5 to 6.0. Depending on the bulk of plasma membrane internalized and the size of the particle, the uptake process involves cytoskeletal components[78] and small guanosine triphosphatases (GTPases) and docking machinery. Guanosine triphosphate (GTP) hydrolysis serves as an important mechanism for controlling intra-cellular membrane traffic and coupling to the cytoskeleton. Cytokines such as IFN-γ can have a major effect on activation and relocation of GTP-binding proteins, contributing to host cell–pathogen interactions.[79]

Proteomic analysis of isolated phagolysosomes has revealed more than 600 constituents, classified according to the source of the membrane and various putative functions.[80] Although most membrane constituents are derived from the plasma membrane, descriptions of contributions from the endoplasmic reticulum have elicited considerable interest, along with different estimates of their extent.[80,81] Another controversial aspect relates to the role of TLR engagement in enhancing the kinetics of the maturation process, a transcription-independent process.[82] Variations on this theme occur, depending on cell type and maturity, whether the extra-cellular cargo is microbial (living or dead) or host derived, and whether the process arises by autophagy (Figure 10-18)[83] rather than by heterophagy. The role of autophagy in cellular resistance to intra-cellular pathogens, such as M. *tuberculosis*, is receiving increasing consideration.[84,85]

Immature DCs are actively endocytic and phagocytic but poor APCs, whereas mature DCs downregulate uptake but acquire highly efficient APC function.[20] Changes associated with DC maturation and antigen presentation are illustrated in Figure 10-19 and Table 10-2. Pathogenic intracellular organisms vary in their subversion of the aforementioned process, interfering with different stages such as cytosolic signaling mechanisms, fusion, or acidification, and in selected cases, inducing a novel membrane composition.[86] Organisms can replicate in immature or mature compartments or can translocate their genome to the cytosol by acid-induced envelope fusion or by disruption of the vacuolar membrane.

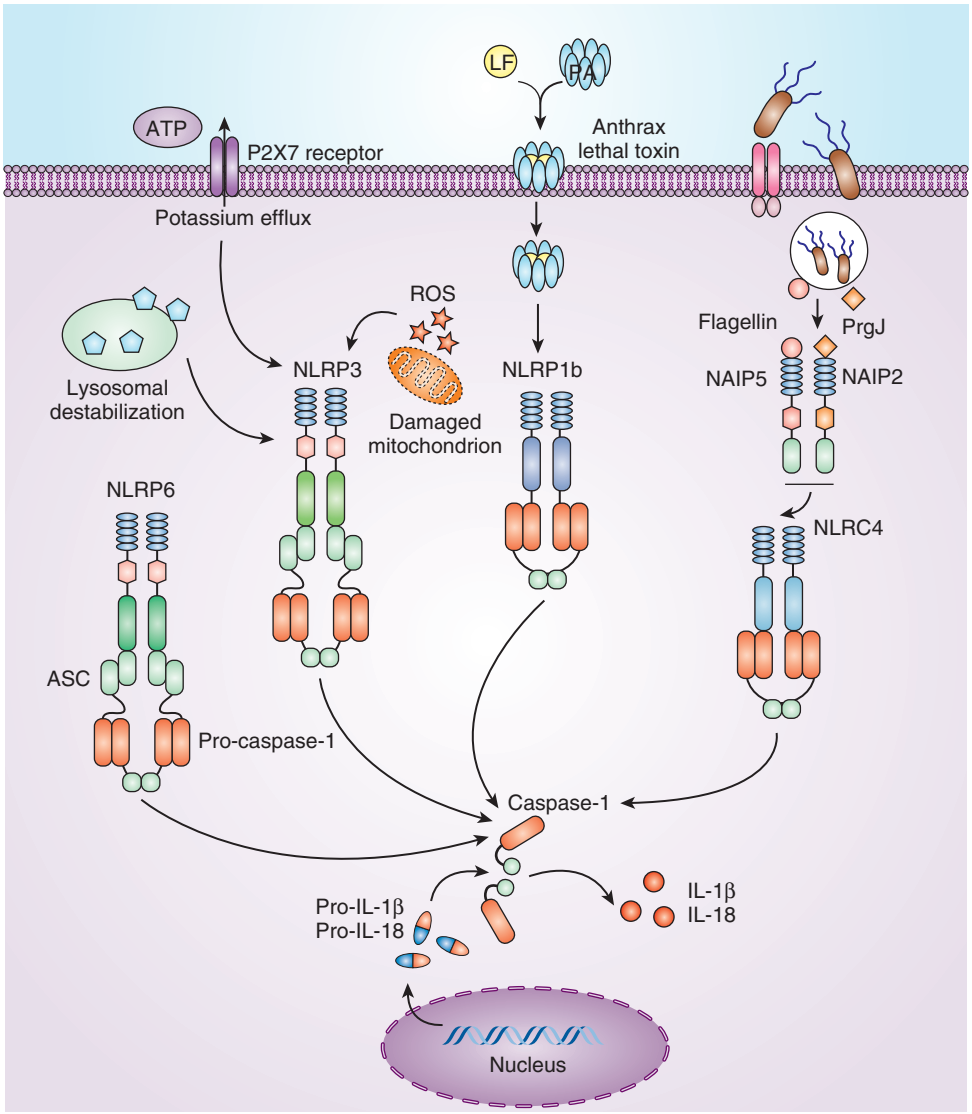

**Figure 10-14** Basic mechanisms of activation of the main nucleotide oligomerization domain (NOD)-like receptor (NLR) inflammasomes. NLRP3 is activated by three common cellular events elicited by different stimuli: potassium efflux; the generation of reactive oxygen species (ROS); and phagolysosomal destabilization and the release of endogenous mediators into the cytosol. NLRP1b is activated by anthrax lethal toxin. In the mouse, NLRC4 is activated by neuronal apoptosis inhibitory protein (NAIP) proteins bound to specific ligands. NAIP5 and NAIP6 bind to bacterial flagellin, whereas NAIP2 binds to the bacterial T3SS component PrgJ. These NAIP-ligand complexes subsequently bind and activate NLRC4. ATP, Adenosine triphosphate; IL, interleukin; LF, lethal factor; PA, protective antigen. *(From Rathinam VAK, Vanaja SK, Fitzgerald KS: Regulation of inflammasome signaling.* Nat Immunol *13:333–342, 2012.)*

## Signaling

The best-characterized signaling responses in macrophages include the TLR,[87] type I IFN,[88,89] and Fc receptor–induced pathways.[90] The various signaling cascades are complex, interact with one another, and result in phosphorylation/dephosphorylation, formation of cytosolic protein complexes, and activation of signaling proteins such as NF-κB, which enter the nucleus to regulate transcription. In the case of TLR-dependent sensing, a restricted number of adapters, such as myeloid differentiation primary-response gene 88 (MyD88), TIRAP-MAL, and Toll/IL-1R (TIR) domain-containing adaptor protein inducing IFN-β (TRIF), channel the flow of information into the cell. Emerging evidence suggests that NTR-induced signaling (e.g., by the β-glucan receptor [Dectin-1] cytoplasmic ITAM-like motif)[59] collaborates with TLR and NLR signaling pathways, with differential involvement of syk and CARD9[91] in effector responses in different mononuclear phagocytes. Distinct but interlinked pathways involve IFN regulatory factors as part of an amplification pathway with broader immunoregulatory functions than anti-viral responses alone. A more recently defined cytosolic specialized antiviral pathway involves interaction with mitochondrial components (Figure 10-15).[73] Cell surface or intra-cellular proteins serve as negative regulators, as exemplified by members of the SOCS family.

Figure 10-19 illustrates the pathway by which effector response–derived antigens are transported to the cytosol during synthesis, are processed in proteasomes, and become associated with class I MHC molecules for presentation at the cell surface. Effector response chaperones, such as heat

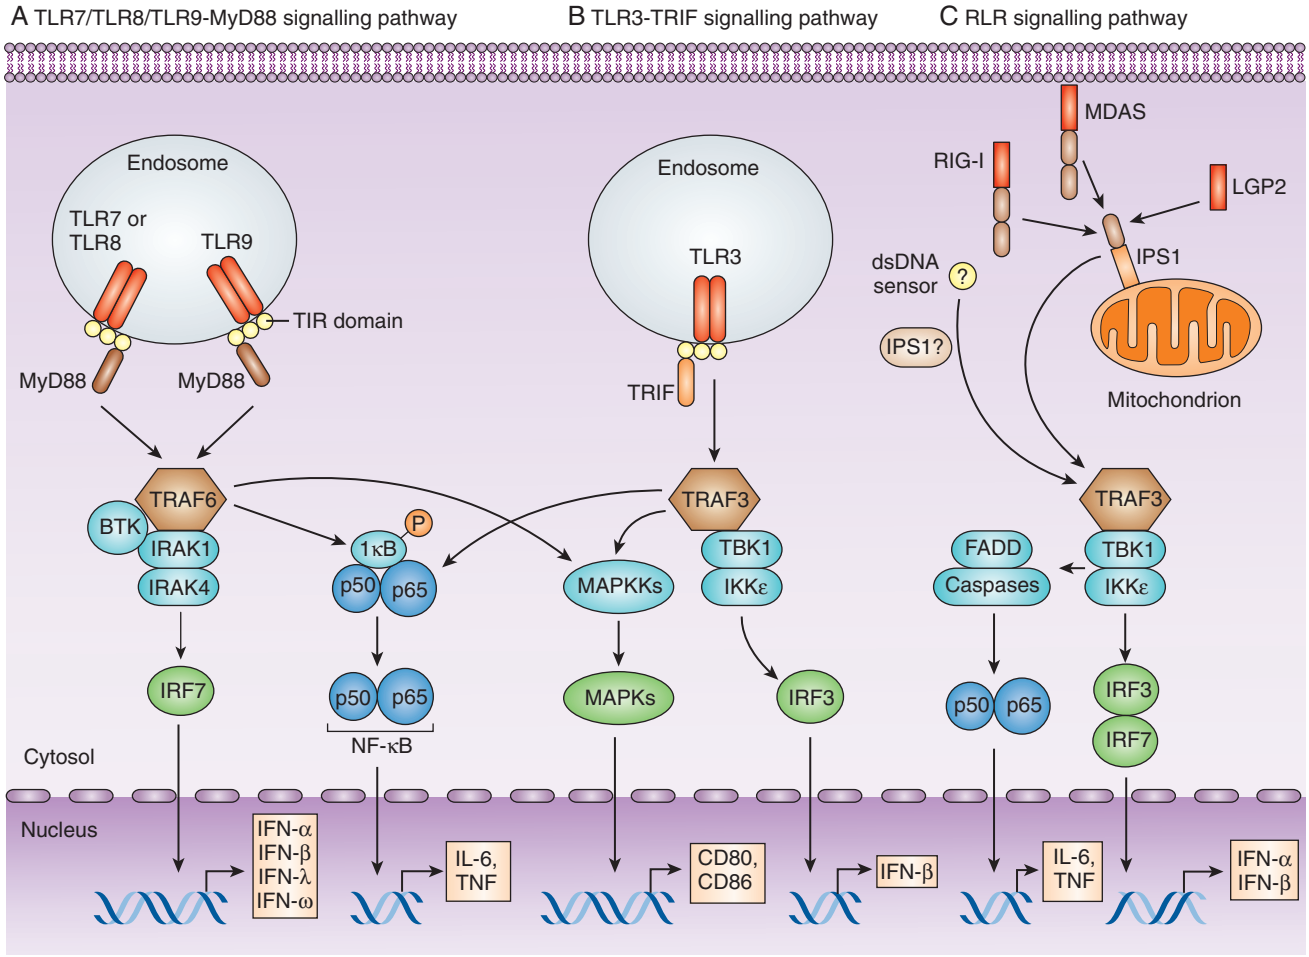

**Figure 10-15** Intra-cellular nucleic-acid sensors and signaling pathways. **A,** Endosomal Toll-like receptor 7 (TLR7), TLR8, and TLR9 recognize RNA and DNA ligands and signal through a key adaptor myeloid differentiation primary-response gene 88 (MyD88) in the cytosol. MyD88 in turn associates with a signal complex comprised of tumor-necrosis factor (TNF)-receptor–associated factor 6 (TRAF6), Bruton's tyrosine kinase (BTK), interleukin-1–receptor (IL-1R)-associated kinase 4 (IRAK4) and IRAK1, which leads to the activation of interferon-regulatory factor 7 (IRF7), nuclear factor-κB (NF-κB), and mitogen-activated protein kinases (MAPKs). Overall, this pathway potently induces the production of high levels of type I interferons (IFNs, such as IFN-α, IFN-β, IFN-λ, and IFN-ω), pro-inflammatory cytokines, and expression of co-stimulatory molecules. **B,** Alternatively, the binding of double-stranded RNA (dsRNA) to endosomal TLR3 triggers a signaling pathway mediated by Toll/IL-1R (TIR) domain-containing adaptor protein inducing IFN-β (TRIF), which involves TRAF3, TANK-binding kinase 1 (TBK1), and inhibitor of NF-κB kinase ε (IKK-ε). Subsequent IRF3 activation leads to IFN-β production. The TLR3–TRIF signaling pathway also activates NF-κB and MAPKs and results in the production of pro-inflammatory cytokines and the expression of co-stimulatory molecules (CD80 and CD86). **C,** The dsRNA receptors retinoic-acid–inducible gene I (RIG-I), melanoma differentiation–associated gene 5 (MDA5), and laboratory of genetics and physiology 2 (LGP2) constitute the third nucleic-acid sensor system, exclusively located in the cytoplasm of most cells. RIG-I, MDA5, and LGP2 signal through a common adaptor molecule IFN-β–promoter stimulator 1 (IPS1), which is associated with the mitochondria. By coupling with TRAF3, TBK1, and IKK-ε, IPS1 directly activates IRF3 and NF-κB through FAS-associated via death domain (FADD), caspase-8, and caspase-10. This pathway induces the production of type I IFNs and other cytokines. dsDNA-induced IFN production involves a yet-to-be defined sensor that signals through certain components of the RIG-I–like receptor (RLR) pathway, such as TBK1 and IRF3. IkB, Inhibitor of NF-κB; MAPKK, MAPK kinase. *(From Gilliet M, Cao W, Liu Y-J: Plasmacytoid dendritic cells: sensing nucleic acids in viral infection and autoimmune diseases.* Nature Rev Immunol *8:594-606, 2008.)*

shock protein, may contribute to the surface delivery of antigens. The inflammasome is another example of a multiprotein assembly within the cytosol by which NLRs bring about IL-1 activation.

Several of the processes already described involve proteolytic enzymes, including cathepsins and caspases, and lipid-interacting chaperones. The ubiquitin pathway provides an important mechanism for cytosolic degradation of proteins. In addition, vacuolar $H^+$ adenosine triphosphatases (ATPases) contribute to acidification in different mononuclear phagocytes, which is especially relevant to osteoclast function. Comparison and further elucidation of the coupling between extra-cellular and intra-cellular signaling pathways in macrophages, DCs, and osteoclasts would be of great interest.

## Efferent Pathways: Gene Expression and Secretion

The complex responses of different mononuclear phagocytes to intrinsic and extrinsic stimuli have been defined by microarray studies and, in some cases, by protein and functional analyses. Although the major differentiation pathways (i.e., macrophages, immature and mature DCs, and osteoclasts) involve selective, stereotypic changes in gene expression, the extensive heterogeneity and plasticity of

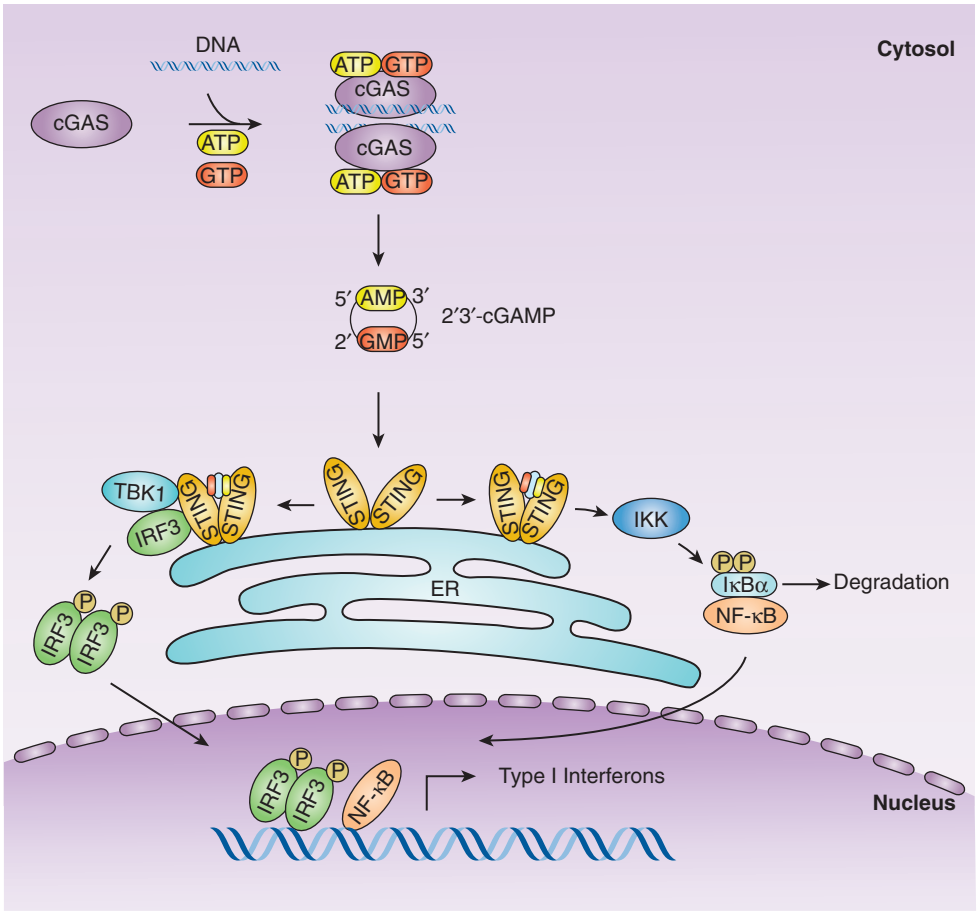

**Figure 10-16** Model for cyclic guanosine monophosphate (GMP)-adenosine monophosphate (AMP) (cGAMP) synthase (cGAS)-mediated cytosolic DNA. Cytosolic DNA activates cGAS to form a dimeric cGAS-DNA complex that synthesizes 2′3′-cGAMP from adenosine triphosphate (ATP) and guanosine triphosphate (GTP). As a high-affinity ligand for STING, 2′3′-cGAMP binds and activates STING through a series of structural changes. Activated STING then recruits TANK-binding kinase 1 (TBK1) to phosphorylate interferon-regulatory factor 3 (IRF3) and activate inhibitor of nuclear factor-κB (NF-κB) kinase (IKK) to phosphorylate IκBα, leading to IκBα degradation. IRF3 subsequently dimerizes and translocates into the nucleus along with NF-κB to induce the production of type I interferons and other cytokines. ER, Endoplasmic reticulum; STING, stimulator of interferon genes. *(From Cai X, Chiu YH, Chen ZJ: The cGAS-cGAMP-STING pathway of cytosolic DNA sensing and signaling.* Mol Cell *54:289–296, 2014.)*

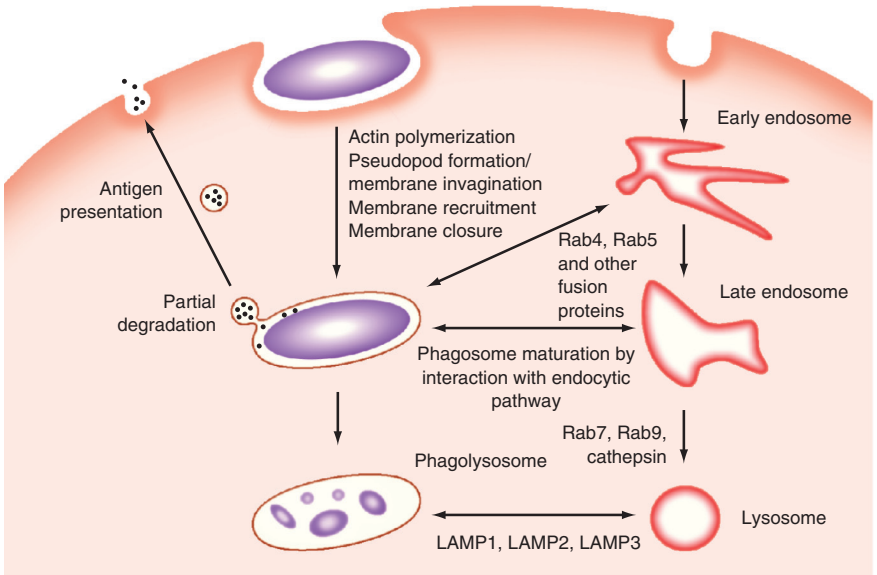

**Figure 10-17** Schematic presentation of phagocytosis and endocytosis. Particulates are taken up by actin-dependent sequential maturation processes involving membrane fusion and fission, which intersect with the endocytic pathway at several stages. Cytosolic small guanosine triphosphatases (GTPases) (Rabs) determine organelle-specific interactions. Membrane is recycled to the plasma membrane with processed antigen (see Figure 10-19). Progressive acidification and delivery of lysosomal hydrolases result in terminal degradation. Compartment membranes express marker proteins such as lysosome-associated membrane protein 1 (LAMP1); the pan-macrophage CD68 antigen is associated with late endosomes and lysosomes.

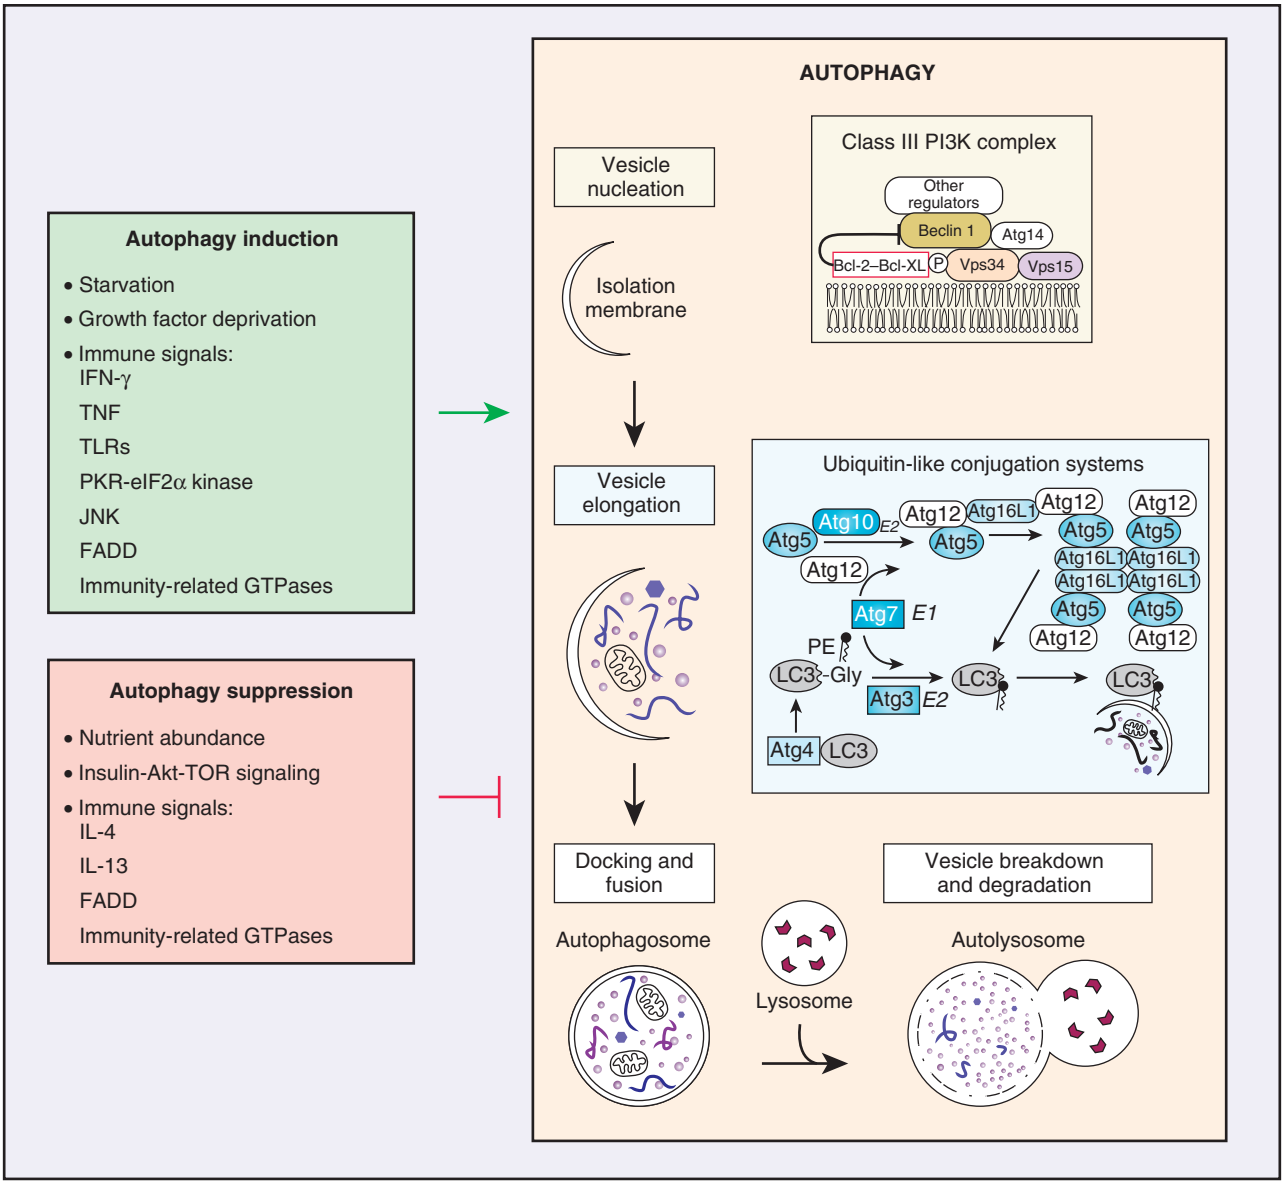

**Figure 10-18** The autophagy pathway and its regulation. The autophagy pathway proceeds through a series of stages, including nucleation of the autophagic vesicle, elongation and closure of the autophagosome membrane to envelop cytoplasmic constituents, docking of the autophagosome with the lysosome, and degradation of the cytoplasmic material inside the autophagosome. Vesicle nucleation depends on a class III PI3K complex that contains various proteins *(light yellow box at right)*, as well as additional proteins that regulate the activity of this complex (such as rubicon, UVRAG, Ambra-1 and Bif-1). Vesicle elongation and completion involves the activity of two ubiquitin-like conjugation systems *(light blue box at right)*. The autophagy pathway is positively regulated *(green box at left)* and negatively regulated *(red box at left)* by diverse environmental and immunological signals. E1 and E2, Ligases for ubiquitin-like conjugation systems; FADD, FAS-associated via death domain; Gly, glycine; GTPase, guanosine triphosphatase; IFN, interferon; IL, interleukin; Jnk, c-Jun N-terminal kinase; PE, phosphatidylethanolamine; PKR, protein kinase R; TLR, Toll-like receptor; TNF, tumor necrosis factor; TOR, target of rapamycin. *(From Virgin HW, Levine B: Autophagy genes in immunity.* Nat Immunol *10:461–470, 2009.)*

phenotypes characterizing these cells in situ have begun to be appreciated only more recently.[4] Macrophages are known to express numerous nuclear receptors,[92] which undergo dynamic changes depending on cellular differentiation and the microenvironment, as well as epigenetic histone modification[93,94] and microRNA expression. Exposure to particular cytokines, hormones, and other stimuli, such as microbial antigens and immune complexes, modulates gene expression profoundly and selectively and induces post-transcriptional and post-translational changes. Through alternative splicing, glycosylation, and poorly characterized protein modifications (e.g., methylation and acetylation of nuclear and cytoplasmic macromolecules), this exposure provides different mononuclear phagocytes with extensive diversity in adaptation and function.

Table 10-4 provides a partial list of macrophage secretory products that include low-molecular-weight metabolites (oxygen, nitrogen, and lipid-derived metabolites) implicated in inflammation and its resolution[95] and in anti-microbial responses. Other products include pro-inflammatory and anti-inflammatory cytokines and neutral proteinases. The cell biology of the secretory pathway in macrophages has only begun to be studied. The release of IL-1β after inflammasome activation is independent of a

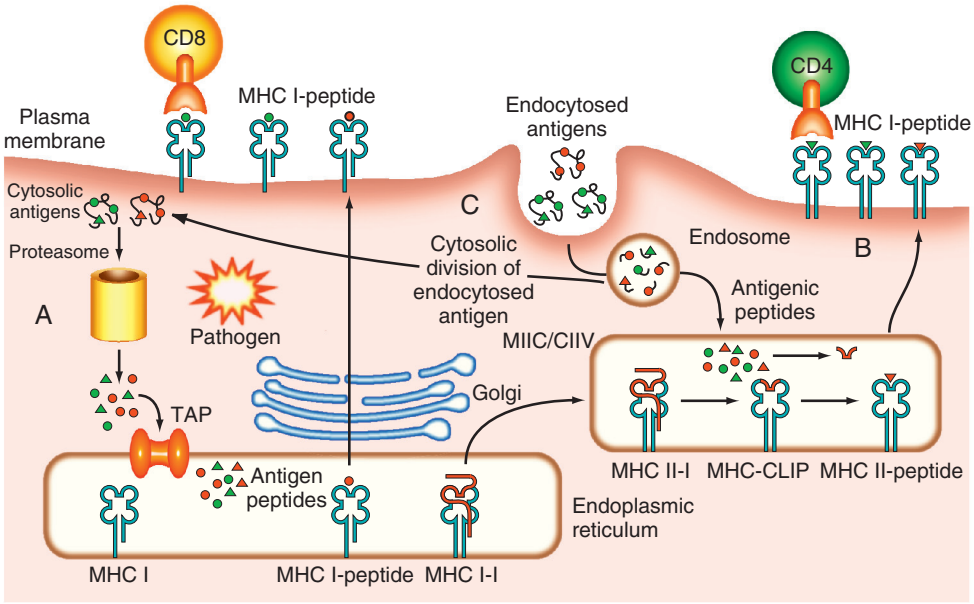

**Figure 10-19** Different antigen-processing pathways for the class I and class II major histocompatibility complex (MHC) molecules.[121] **A,** Class I MHC molecules present peptides that are derived primarily from endogenously synthesized proteins of self or pathogen origin. These proteins are degraded into peptides by the proteasome and are transported through the transporters of antigen-processing (TAP) molecules into the endoplasmic reticulum for loading on class I MHC molecules. **B,** Class II MHC molecules present proteins that enter the cell through the endocytic route. During maturation of class II MHC molecules, they are prevented from binding to endogenous antigens in the endoplasmic reticulum by association with the invariant chain (Ii). Invariant chain–class II MHC complexes (MHC II-Ii) move through the Golgi to the MHC II loading compartment/MHC II vesicles (MIIC/CIIV) compartment, where the invariant chain is degraded to class II–associated invariant-chain peptide (CLIP). CLIP is removed from the CLIP–MHC class II (MHC-CLIP) complexes and is exchanged for antigenic peptide. **C,** Dendritic cells can endocytose antigens from other cells and cross-present them to $CD8^+$ cytotoxic T lymphocytes. In most cases, these antigens also are processed into the class II MHC presentation pathway for recognition by $CD4^+$ T helper cells. *(From Heath WR, Carbone FR: Cross-presentation in viral immunity and self-tolerance.* Nat Rev Immunol *1:126–134, 2001.)*

canonical signaling sequence. The differential effect of T helper type 1 and 2 cytokines on nitric oxide production versus its destruction is thought to be relevant to microbicidal mechanisms versus repair.[4] The secretory activities of DCs and osteoclasts are relevant to their specialized functions (e.g., lymphocyte activation and bone remodeling) and depend on polarized secretion.

Table 10-5 shows a classification of characteristic effects induced by prototypic activating and inhibitory stimuli. It is convenient to distinguish the phenotype of mononuclear phagocytes stimulated by an innate stimulus, including exposure to microbial products such as LPS; by a classic immune-activating cytokine such as IFN-γ; and by IL-4/IL-13 induction of an alternative activation pathway.[4] Other stereotypic responses are induced by immune complexes that selectively modulate IL-12/IL-10 expression.[96] Innate and immune cytokine stimuli are able to potentiate one another.

Conversely, deactivating stimuli such as IL-10 and transforming growth factor (TGF)-β and glucocorticosteroids[97] induce their own distinctive patterns of gene expression. Upregulation of CD163, a hemoglobin-haptoglobin SR, is a striking example of glucocorticosteroid-enhanced endocytic function.[98] Stimulation of the vagus nerve attenuates macrophage activation by activating the JAK2/STAT3 signaling pathway.[99] Deactivation of macrophages plays a critical role in limiting pro-inflammatory activation induced by cytokines (e.g., IFN-γ) and opsonic (FcR) and non-opsonic stimulation (TLR, NLR, and inflammasomes), acting via a range of signal transduction pathways and naturally occurring antagonists. Deactivation of macrophages is a particular feature of phagocytic uptake of apoptotic cells (see Figure 10-9) thought to be mediated by TGF-β, prostaglandin $(PG)E_2$, and IL-10, which also inhibit the generation of reactive nitrogen and oxygen species. The resolvins and protectins derive from the omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) produced by the cyclooxygenase (COX)-2 pathway, especially in the presence of aspirin. They inhibit production and recruitment of leukocytes to sites of inflammation and counteract pain.[100]

Plasma membrane signals to deactivate macrophages arise from transligation of CD200 (expressed by many cells, including innate-activated macrophages) and its signaling immunoglobulin superfamily (IGSF) counterpart CD200R, expressed selectively by macrophages.[63] Another inhibitory receptor pair consists of signal regulatory protein α (SIRPα) and CD47[64]; cytosolic inhibitors include the SOCS proteins.[22] These extra-cellular mediators and poorly defined interactions with surface expressed molecules make the different APCs reciprocally interactive with other immune cells (helper and regulatory CD4 T cells, CD8 T cells, natural killer cells, and natural killer T cells) and with nonhematopoietic cells such as fibroblasts, epithelium, and neurons and with malignant cells.[101] Induced responses on macrophages include altered class II MHC and co-stimulatory molecule expression, marker antigens involved in cellular interactions, phagocytosis and antigen presentation, and altered secretion. As a result, different mononuclear phagocytes are able to modulate their interactions

**TABLE 10-4** Selected Products Secreted by Macrophages

| Proteins | Product | Comment |
|---|---|---|
| Enzymes | Lysozyme | Bulk product |
| | Urokinase-type plasminogen activator | Regulated by inflammation |
| | Collagenase | Regulated by inflammation |
| | Elastase | Regulated by inflammation |
| | Metalloproteinases | Also inhibitors |
| | Complement | All components and regulators |
| | Arginase | Alternative activation |
| | Angiotensin-converting enzyme | Induced glucocorticoids, granulomas |
| | Chitotriosidase | Gaucher's disease, lysosomal storage disease |
| Inhibitors | Acid hydrolases | All classes (mainly intra-cellular) |
| | TIMP | |
| Chemokines | Many C-C, C-X-C, CX3C (e.g., MCP, RANTES, IL-8) | Initiate short- and long-term recruitment of myeloid and lymphoid cells |
| Cytokines | IL-1β, TNF, IL-6, IL-10, IL-12, IL-18, IL-23 | Pro-inflammatory and anti-inflammatory |
| | Type I interferon | Also antagonists (e.g., IL-1Ra) |
| | | Autocrine and paracrine amplification |
| Apolipoproteins | Apolipoprotein E | Local source, bone marrow origin after adoptive transfer |
| Growth/differentiation factors | TGF-β | Also other family members (activins) |
| | M-CSF | Myeloid growth and differentiation |
| | GM-CSF | |
| | FGF | Fibrosis |
| | PDGF | Repair |
| | VEGF | Angiogenesis |
| Opsonins | Fibronectin, pentraxin (PTX3) | Additional uncharacterized receptor on macrophages |
| Soluble receptors | Mannose receptor | Soluble mannose receptor |
| Cationic peptides | Defensins | Subpopulations and species variation |
| Lipids | Procoagulant | Initiation of clotting |
| | Arachidonate metabolites | Pro-inflammatory and anti-inflammatory mediators |
| | Prostaglandins | |
| | Leukotrienes | |
| | Thromboxanes | |
| | Resolvins, maresins | |
| Metabolites | Reactive oxygen intermediates | Respiratory burst and signaling |
| | Reactive nitrogen intermediates | Anti-microbial and signaling |
| | Hemoglobin breakdown (bile pigments) | |
| | Iron, vitamin $B_{12}$ binding protein | |
| | Vitamin D metabolites | Cell regulation, including osteoclasts |

FGF, Fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; MCP, monocyte chemotactic protein; M-CSF, macrophage colony-stimulating factor; PDGF, platelet-derived growth factor; RANTES, regulation upon activation normal T cell expressed and presumably excreted; TGF, transforming growth factor; TIMP, tissue inhibitor of metalloproteinase; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

with CD4 T lymphocytes, with endothelial and other cell types, with extra-cellular matrix, and with bone to induce trophic and cytostatic/cytocidal and catabolic effects.

Human inborn errors or defects in macrophage responses to intra-cellular pathogens such as mycobacteria[102] have validated studies on cell activation in the mouse. The immunosuppressive effects of macrophages in immune tolerance to an allogeneic fetus have been ascribed to induction of indoleamine-2,3-dioxygenase, which catabolizes the essential amino acid, L-tryptophan.[103] Macrophage products act mainly locally but also can have profound systemic effects, regulating metabolic and regulatory responses within the host. These effector programs and products provide targets for pharmacologic intervention.

## MACROPHAGE PLASTICITY

The question of macrophage plasticity has become interesting because of the extensive heterogeneity of macrophages in different organs, the diversity in phenotypes associated with cell activation, and the power of contemporary gene expression analysis and its relevance to potential modulation by therapy. Although no simple conclusions can yet be drawn of its extent and mechanisms, we summarize aspects and limitations of current knowledge.

It is useful to distinguish differentiation of mononuclear phagocytes and the microheterogeneity of resident cells in different tissue microenvironments, from the biosynthetic and secretory adaptation of blood monocyte–derived mononuclear phagocytes to inflammatory, immune, and metabolic stimuli. Morphology, differential antigen expression and in situ analysis of RNA and protein expression have all contributed to our still limited understanding of cellular heterogeneity. Lineage-specific growth and differentiation factors, selective expression of transcription factors, and enhancers, epigenetic modifications and local and systemic modulators such as retinoids, lipids, and microbial products all contribute to cell heterogeneity. For example, in vitro

ACE, Angiotensin-converting enzyme; FcR, Fc receptor; IFN, interferon; IL, interleukin; iNOS, inducible nitric oxide synthase; LGP47, lysosomal glycoprotein; MARCO, macrophage receptor with collagenous structure; MDC, macrophage-derived chemokine; MHC, major histocompatibility complex; MR, mannose receptor; NADPH, nicotinamide adenine dinucleotide phosphate-oxidase; NO, nitric oxide; ROI, reactive oxygen intermediates; TARC, thymus and activation-regulated chemokine; TNF, tumor necrosis factor; Treg, regulatory T cell.

and in vivo studies of the actions of cytokines such as IFN-γ and IL-4/IL-13 and of sensors such as the TLRs and opsonic phagocytic receptors have provided paradigms of cell activation phenotypes, termed variously classic, alternative and innate, or M1/M2 activation. The characterization and limitations of this terminology have been extensively discussed in recent reviews.[104] It has been proposed that a spectrum of activation states is more appropriate than simple binary alternatives, and recommendations have been put forward to standardize and define experimental specificity.[105] A general conclusion is that potential markers should be used in combination to define a signature, rather than individually.

However, to gain insight into the question of plasticity, the following considerations must be kept in mind for further research into flexibility and manipulation of phenotypes by microarray, RNA sequencing, and in situ gene and protein analysis. How stable, complete, and reversible are the signatures obtained after single and multiple stimuli? How do they evolve in the course of a dynamic process, at different times, and at different locations? How can we distinguish changes in cell populations and at the single cell level? To what extent do species differences apply, for example, between humans and rodents? What epigenetic mechanisms are at play? What do we mean by terms such as priming and tolerance? Above all, is it possible to convert a particular macrophage phenotype from one state to another? Although it has been reported that one type of tissue macrophage can be changed to another by adoptive transfer and we know that differentiated macrophages can be derived from induced pluripotent precursors derived from other somatic cells,[106] a great deal more needs to be done to validate their correspondence to macrophages in vivo. It may be premature to conceive of direct switching of pro-inflammatory cells, for example, to anti-inflammatory, trophic, or regulatory macrophages or to induce tumor-promoting macrophages to become tumoricidal by simple pharmacologic means. Clearly the full complexity of phenotypic heterogeneity and its regulation requires a great deal of further systematic investigation.

## Relevance to Selected Rheumatic Diseases

Although the different mononuclear phagocytes have been addressed as part of a general host homeostatic system, there are good examples in human rheumatic diseases and in animal models of arthritis in which these cells play a role in the local initiation or effector phase of the disease. Primary defects in osteoclast differentiation and function contribute to osteopetrosis or, if overactive, osteoporosis.

We have referred to autoinflammatory syndromes and newly discovered cytosolic receptors. Gout might also fall in this category because uric acid crystals provide a metabolic stimulus for inflammasome activation. Macrophages play a role in the pathogenesis and complications of osteoarthritis, including the response to foreign implants. DCs and macrophages play a part in the induction and effector mechanisms of autoimmune arthritis, in concert with T lymphocytes and B lymphocytes and their products, immune complexes, and complement. Co-stimulatory receptors such as PD-1 and its ligands already provide potential targets for antibody therapy. The catabolic role of TNF, IL-1, neutral proteinases, reactive oxygen radicals, and arachidonate metabolites is well known. Less appreciated are the trophic interactions of macrophages with fibroblasts through production of TGF-β, growth and angiogenic factors, and modulation by alternative activation pathways.[107] Type I IFNs, produced by macrophages and other cells, play an important amplification role in autoimmune inflammation (e.g., SLE).

Although animal models may not mimic the natural diseases in humans, more recent examples suggest that APC membrane receptors involved in recognition of modified self and foreign microbial ligands could be relevant to arthritis; examples include streptococcal rheumatic disease and exacerbation of recurrent arthritis by zymosan in T cell transgenic mice, acting via Dectin-1, the APC receptor for β-glucans.[108] In addition, inhibitory plasma membrane receptor interactions (CD200/CD200R) limit macrophage activation and collagen-induced murine arthritis.[63,109] Impaired clearance of apoptotic cells by (uncharacterized) C1q receptors of mononuclear phagocytes may contribute to autoimmune diseases such as lupus.[67] Finally, macrophages and DCs could contribute to wider connective tissue disorders, such as scleroderma, because they are able to regulate fibroblast and matrix synthesis and turnover through metalloproteinases and TGF-β; dysregulation of these pathways has been neglected as a pathogenetic mechanism in these systemic diseases.

## ISSUES FOR FURTHER INVESTIGATION

As we take stock of how increasing knowledge of mononuclear phagocyte biology has affected pathogenesis and therapy of rheumatic diseases, additional questions arise regarding basic mechanisms and new selective targets. Treating macrophages, DCs, and osteoclasts as specialized forms of a unitary mononuclear phagocyte family helps to bring out their common and distinctive properties. Selective expression and signaling pathways of pattern recognition receptors by macrophages and DCs are still poorly characterized; regulation of TLR signaling has already received considerable attention as a possible drug target. Discrimination of microbial and host-derived ligands may account for mimicry and autoantigen cross-reactivity, but mechanisms for regulating homeostatic and tolerogenic responses are still unclear.

On the effector side, success with anti-TNF monoclonal antibodies suggests that targeting of individual effector molecules can succeed, especially when these are expressed at the cell surface and are proximal in cascade reactions, although further study is needed to account for resistance to therapy in a group of patients. The impact of anti-TNF therapy on macrophage functions and mechanisms for resistance to TNF blockade are poorly understood. The role of inhibitory/activating pairs of surface molecules as modulators of APC pathways is unexplored and is likely to move to center stage. One neglected aspect of differentiation and function for osteoclasts and granuloma macrophages is the mechanism of fusion and the possible functional significance of multinuclear giant cell formation. Basic knowledge is still lacking and may provide useful insights into the pathogenesis of metabolic bone diseases and enhanced perception of links with the immune system, both innate and adaptive.

Although powerful tools of messenger RNA and proteomic analysis and gene silencing by RNA interference inhibition have become available, the heterogeneity and complexity of mononuclear phagocytes in human tissues, especially at early stages of disease, need improved characterization in situ and at different sites. Much remains to be learned concerning trophic processes and repair and their relationship to the resolution of inflammation and fibrosis. These processes involve cell-cell interactions that are poorly understood but are increasingly amenable to investigation.

CHAPTER 11

# Neutrophils

Binita Shah • Nathalie Burg • Michael H. Pillinger

**KEY POINTS**

- **Neutrophils are myeloid-lineage cells characterized by the presence of granules that contain enzymes and other potentially toxic agents involved in host defense.**
- **Neutrophils are short-lived, terminally differentiated cells that exist primarily in the bloodstream, where they participate in host surveillance of foreign organisms.**
- **Neutrophils function in instances of acute inflammation and provide an essential defense against acute bacterial infections. Abnormalities of neutrophil function are uncommon and impair ability to respond to life-threatening infections.**
- **Key functions of neutrophils include phagocytosis and degradation of foreign organisms, such as bacteria, through activation of proteases and other antibiotic molecules, as well as generation of toxic oxygen radicals.**
- **Neutrophils play a role as major inflammatory cells in many rheumatic conditions and may be attracted into tissues by noninfectious stimuli such as activated complement components and lipid inflammatory mediators.**
- **Neutrophil extra-cellular traps are aggregates of extruded neutrophil chromatin and granule enzymes that may trap and destroy bacteria but also play a role in promoting inflammation and thrombosis.**

Neutrophils (polymorphonuclear neutrophils [PMNs]) belong to the family of polymorphonuclear leukocytes, which are hematopoietically derived cells that share the features of a multilobed nucleus and highly developed intracytoplasmic granules (hence the alternative term *granulocytes* for this family of cells). On the basis of the histocytochemical staining properties of their respective granules, three classes of polymorphonuclear leukocytes have been identified: neutrophils, eosinophils, and basophils. Whereas neutrophil granules stain with neutral dyes, the granules of eosinophils are most effectively stained with acidic dyes such as eosin, and basophil granules stain with basic dyes. In a standard polychromatic Wright stain of a peripheral blood smear, the cytoplasm of neutrophils, eosinophils, and basophils appears blue-pink, pink, and blue, respectively. These classes of polymorphonuclear leukocytes differ not only in appearance but also in biochemistry and function. Polymorphonuclear leukocytes constitute an important part of the organism's system of innate immunity; their responses to foreign organisms, antigens, or both are preprogrammed and do not depend on prior exposure to the foreign particle.

Neutrophils are the body's first line of defense against foreign invaders and constitute the major cell type involved in acute and some forms of chronic inflammation. The importance of neutrophils in bacterial defense is illustrated by patients who have hereditary defects in neutrophil function and are prone to repeated and often life-threatening infections. Neutrophils are the most prevalent leukocytes in the bloodstream, typically constituting more than 50% of all bloodstream leukocytes. During bacterial infection, the percentage of neutrophils may increase to 80% or more. In contrast, tissue concentrations of neutrophils during periods of homeostasis are quite low but increase locally in response to infection or other triggers. Neutrophils may be considered to be surveillance cells that sweep through the bloodstream, scanning for tissue infections or other inflammatory events. Unfortunately, the capacity of neutrophils to destroy foreign organisms is matched in some circumstances by a capacity for host tissue destruction. In this chapter we review neutrophil development, structure, and function, the role of neutrophils in protecting against infection, and the role and impact of neutrophils in the pathogenesis and pathophysiology of immune deficiency and autoimmune and autoinflammatory diseases.

## NEUTROPHIL DEVELOPMENT, MORPHOLOGY, AND CONTENT

### Neutrophil Myelopoiesis and Clearance

The abundance of neutrophils in the bloodstream is duplicated in the bone marrow, where 60% of hematopoietic capacity may be dedicated to neutrophil production. Daily, $10^{11}$ neutrophils are released into the bloodstream. Neutrophil development in the marrow takes about 14 days, originating with the hematopoietic stem cell. Stem cells fated to become neutrophils first differentiate into myeloblasts, which retain the capacity to develop into eosinophils, basophils, and neutrophils. Subsequent differentiation leads to the neutrophilic promyelocyte, a dedicated precursor of the neutrophil, and proceeds through the stages of neutrophilic myelocyte, metamyelocyte, band cell, and mature neutrophil. At the metamyelocyte stage, neutrophil mitosis ceases, whereas neutrophil development and organization of granules continue. Only the mature neutrophil demonstrates the classic feature of a multilobed nucleus. Neutrophils are

terminally differentiated; they neither divide nor, as a general rule, alter their gross phenotype after their release from the marrow. However, in the setting of certain infections, such as helminths, some neutrophils show a distinct profile of gene expression and a ring-form nucleus, in contrast to the typical multilobed cell seen in the peripheral blood.[1]

Given the origin of neutrophils from pluripotent stem cells, as well as the precise phases of their development, the mechanisms regulating neutrophil differentiation are of considerable interest. Although this process remains incompletely understood, studies have emphasized the role of a particular complement of transcription factors and cytokines that seem to direct the early cells toward neutrophil development. Several myeloid factors are necessary for the transcriptional regulation of neutrophils, including LEF-1, CCAAT enhancer binding proteins α and ε (C/EBPα and C/EBPε), and GFI-1. Principal among the cytokines regulating granulopoiesis is granulocyte colony-stimulating factor (G-CSF). G-CSF effects include induction of myeloid differentiation, proliferation of granulocyte precursors, and release of mature neutrophils from the marrow.[2] Biologic effects of G-CSF are mediated through its receptor (G-CSFR or CD114), a member of the class I cytokine receptor family. Although other hematopoietic cytokines contribute to granulopoiesis in vivo (including granulocyte-macrophage colony-stimulating factor [GM-CSF], interleukin [IL]-6, and IL-3), their individual presence is not essential as demonstrated by murine knockout experiments.

Once mature, neutrophils exit the bone marrow through the tight-fitting pores of the sinusoidal endothelium and enter the circulation, a process called *transcellular migration*.[3] Neutrophils released from the marrow have a bloodstream half-life of approximately 6 hours and a tissue half-life only marginally longer. Neutrophil life spans may be modulated by soluble signals; when exposed to stimuli such as tumor necrosis factor (TNF) and Fas (CD95) ligand, neutrophils undergo apoptosis or programmed cell death.[4,5] The high output and short half-life of neutrophils imply that neutrophil clearance mechanisms must exist. Recently, the stromal-derived factor 1 (SDF-1)/CXC chemokine receptor 4 (CXCR4) signaling system has been implicated in neutrophil clearance. CXCR4, a G protein–coupled receptor, is expressed at low levels in the mature neutrophil. As they age, neutrophils alter their phenotype and upregulate CXCR4. This change supports homing to the bone marrow via the chemoattractant SDF-1 (also known as CXCL12). Once back in the marrow, senescent neutrophils are phagocytosed by stromal macrophages.[6] Senescent or apoptotic bloodstream neutrophils are also cleared by liver and spleen macrophages (i.e., the reticuloendothelial system). Although little is known about the molecular mechanisms underlying neutrophil clearance in the liver and spleen, upregulation of the adhesion molecule P-selectin on Kupffer cells appears to be relevant. It remains uncertain whether tissue neutrophils are cleared primarily via local macrophages or if they first traverse through the lymphatic drainage system.

## Neutrophil Morphology and Contents

Neutrophil nuclei tend to have more lobes (typically three to five) than do the nuclei of other polymorphs (Figures 11-1 and 11-2). The multilobed nature of the neutrophil nucleus reflects chromatin condensation, which suggested that neutrophils might be incapable of transcription; it is now known, however, that neutrophils retain the capacity for both constitutive and stimulated protein synthesis, albeit at a limited rate.

Neutrophil granules identifiable by classic histochemical staining comprise two classes (Figures 11-1 and 11-2). Special techniques are required to recognize and identify two additional classes of granules.

### Primary Granules

Neutrophil *primary granules* form first and, by virtue of their staining tendencies (i.e., affinity for the basic dye azure A), are also referred to as *azurophilic granules*.[7] These granules are oval or round and vary in size. They are similar, and functionally equivalent, to the lysosomes of other cells. Characteristic of azurophilic granules is the presence of myeloperoxidase (MPO), an enzyme that catalyzes the

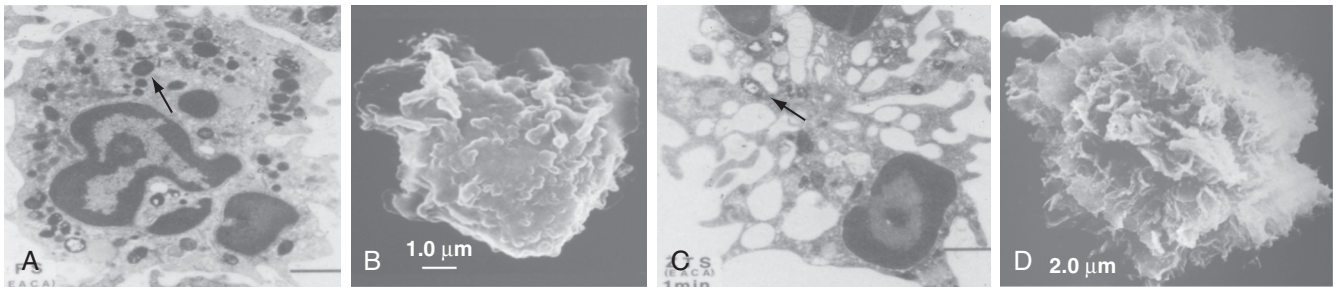

**Figure 11-1** Resting and stimulated neutrophil morphology. **A** and **B,** Transmission **(A)** and scanning **(B)** electron micrographs of resting neutrophils. In **A,** note the multilobed nucleus and the rich population of granules. At least two populations of granules may be discerned: The larger, darker granules represent the primary (azurophilic) granules, whereas the smaller, slightly paler granules are predominantly secondary (specific) granules and may include a population of gelatinase granules (the *arrow* indicates a primary granule). In **B,** note the relatively smooth surface area with some membrane surface irregularities. **C** and **D,** Transmission **(C)** and scanning **(D)** electron micrographs of neutrophils 1 minute after stimulation with zymosan. The cellular diameter is enlarged, and the overall surface (plasma) membrane area is greatly increased. Most of the membrane contributing to the increased surface area is supplied via the fusion of internal granule membranes with the plasma membrane. In **C,** this fusion is apparent as the depletion of granules, leading to an appearance of empty vesicles (the *arrow* indicates a partially depleted primary granule; clear circular areas represent fully depleted vesicles whose membranes are fused to the plasma membrane). In **D,** this fusion is apparent as the increase in plasma surface membrane extensions, known as *lamellipodia. (Courtesy G. Weissmann, NYU School of Medicine.)*

formation of hypochlorous acid from chloride in the presence of hydrogen peroxide ($H_2O_2$) (see the following Respiratory Burst). The presence of large amounts of this enzyme in azurophilic granules lends collections of neutrophils (i.e., pus) their typical greenish-yellow color. Consistent with their role as lysosomes, azurophilic granules also contain a variety of proteases and other enzymes including elastase, lysozyme, acid phosphatase, cathepsins, and enzymes directed at nucleic acids and sugars (Table 11-1). At the membrane level, however, they differ from true lysosomes in their lack of lysosome-associated membrane proteins (LAMPs)-1 and -2 and the mannose-6-phosphate receptor system.[8]

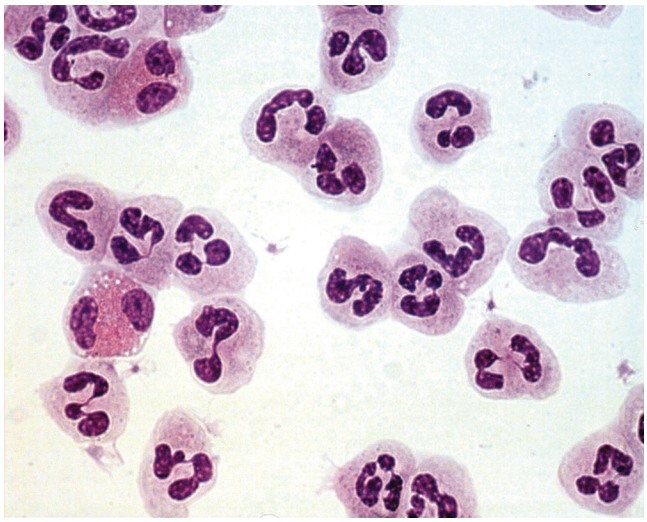

**Figure 11-2** Resting neutrophils and eosinophils under light microscopy. A blood smear stained with hematoxylin and eosin shows neutrophils and eosinophils; the three-lobulated nucleus (polymorphonuclear) cells are characteristic of neutrophil structure. Two eosinophils are distinguished by their bilobed nuclei and pink-stained granules (eosin stains basic structures). *(Courtesy K.A. Zarember, Laboratory of Host Defenses, National Institute of Allergy and Infectious Diseases, National Institutes of Health.)*

## Secondary Granules

In contrast to primary or azurophilic granules, neutrophil *secondary granules* constitute a population unique to neutrophils, a fact reflected in the alternatively employed nomenclature of *specific granules*. Specific granules possess an extensive array of membrane-associated proteins, including cytochromes, signaling molecules, and receptors. Specific granules constitute a reservoir of proteins destined for topologically external surfaces of phagocytic vacuoles and the plasma membrane (Table 11-1).[7] One particularly important family of proteinases found in neutrophil-specific granules are the matrix metalloproteinases (MMPs), including neutrophil collagenase–2 (MMP-8), gelatinase-B (MMP-9), stromelysin (MMP-3), and leukolysin (MMP-25). MMPs are stored as inactive proenzymes and undergo proteolytic activation after specific granule fusion with the phagocytic vacuole, along with interaction with azurophilic granule contents. MMP activation confers upon neutrophils the ability to alter and degrade integral membrane components of phagocytosed bacteria. Neutrophil MMP function is not limited to bacterial killing, however. For example, MMPs are also important for neutrophil extravasation and diapedesis (see the following discussion).[9]

Azurophilic and specific granules also contain antimicrobial proteins and peptides that are the cornerstone of innate immunity. A detailed description of the neutrophil's armamentarium against foreign invaders is beyond the scope of this chapter, but a few mechanisms warrant discussion. Elastase, mentioned previously, aids in the killing of Gram-negative bacteria via degradation of bacterial outer membrane protein A.[10] Elastase-deficient mice are more susceptible to infection with Gram-negative (but not Gram-positive) organisms than are wild-type mice. The defensins, stored in azurophilic granules, accumulate in mg/mL concentrations in phagocytic vacuoles (discussed later) and render target cell membranes (e.g., from bacteria) permeable. Bactericidal/permeability-inducing protein, also stored in azurophilic granules, acts in concert with the defensins;

**TABLE 11-1** Neutrophil Granule Contents

it potently neutralizes endotoxin and is cytotoxic to Gram-negative bacteria. Bactericidal/permeability-inducing protein also enhances the activity of secretory phospholipase $A_2$, which has activity against Gram-negative and Gram-positive bacteria. Lactoferrin, which is found in specific granules, deprives microorganisms of iron and has antiviral and antibacterial effects. Other granule-associated proteins such as cysteine-rich secretory protein 3 (CRISP3) and ficolin 1 have recently been described, although their functions are still unclear.

### Gelatinase Granules and Secretory Vesicles

Special techniques have confirmed the existence of two additional classes of vesicles. *Gelatinase granules* are identical in size to specific granules and share some common proteins. As their name implies, however, gelatinase granules are distinguished by their high concentrations of gelatinase, a latent enzyme with the capacity for tissue destruction.[11] *Secretory vesicles* are smaller and lighter than the other classes and do not seem to contain proteolytic enzymes.[12] Rather, secretory vesicles are noteworthy for an extensive complement of membrane-associated proteins, including receptors otherwise identified with the plasma membrane. These and other data suggest that the secretory vesicle is a reservoir of neutrophil plasma membrane and other membrane proteins (Table 11-1).

Neutrophil granule contents play important roles beyond their direct anti-microbial effects, including amplifying or dampening innate and adaptive immune responses. Lactoferrin released during phagocytosis inhibits proliferation of mixed lymphocyte cultures in vitro by decreasing release of IL-2, TNF, and IL-1β. On the other hand, proteinase 3 augments release of active TNF and IL-1β in monocyte/neutrophil co-cultures by releasing the membrane-bound forms of these cytokines.[13] Gelatinase B converts latent IL-1β into its active form and potentiates IL-8 activity by truncating this chemoattractant and increasing its release, consequently amplifying neutrophilic influx.[14,15] Neutrophil elastase may also play a pro-inflammatory role by virtue of its ability to cleave and disrupt phosphatidyl serine receptors on macrophages. Apoptotic cells undergo membrane alterations that lead to expression of phosphatidyl serine on their outer membrane surface, and interaction of phosphatidyl serine with its receptor leads to macrophage responses that downregulate inflammation through the generation of transforming growth factor (TGF)-β.[16] By disrupting these interactions, neutrophil elastase may permit inflammation to continue.

## NEUTROPHIL ACTIVATION AND SIGNAL TRANSDUCTION

For bloodstream neutrophils to destroy foreign targets in the periphery, they must first sense the presence of such targets at a distance. They must then attach to the activated endothelium of blood vessels through multiple interactions involving adhesion molecules and their receptors (rolling and adhesion). After passing through the endothelium of postcapillary venules (diapedesis), neutrophils migrate to the source of the signal (chemotaxis). Finally, neutrophils must encounter a target, engulf it, and destroy it. Collectively, the processes that allow neutrophils to respond this way are referred to as *neutrophil activation*. Because of the potential for tissue destruction, neutrophil activation must be carefully regulated. The internal responses through which a cell translates an encounter with a stimulus into a particular phenotypic response are termed *signal transduction* (Figure 11-3).[17]

### Stimuli and Receptors

Classic neutrophil chemoattractants include lipid mediators (e.g., leukotriene $B_4$ [$LTB_4$] and platelet-activating factor) and proteins/peptides (e.g., formylated peptides, the complement split product C5a, and IL-8). In vivo, chemoattractants are formed at sites of inflammation—either produced at the site by inflammatory cells (e.g., $LTB_4$ or IL-8) or liberated from already synthesized proteins, as in the case of C5a. The ability of formylated peptides such as *N*-formyl-methionyl-leucyl-phenylalanine (FMLP) to stimulate neutrophils probably represents a particularly ancient arm of the innate immune response because prokaryotic cells but not eukaryotic (e.g., human) cells synthesize proteins whose first amino acid is a formylated methionine, allowing the more advanced organisms to recognize the more primitive ones. In addition to their attractant activities, chemoattractants also stimulate most other aspects of neutrophil activation. Their individual potencies for particular responses differ, however, suggesting that they serve overlapping but distinct functions in neutrophil activation.[18] CXC chemokines are a group of chemoattractants characterized by the presence of two N-terminal cysteines ("C") separated by any other amino acid ("X") at the carboxy terminus. CXC chemokines that play a role in neutrophil recruitment include IL-8 (CXCL8), KC (CXCL1), and macrophage inflammatory protein (MIP)-2 (CXCL2).

Bloodstream activation of neutrophils depends on the presence of specific surface receptors. Most chemoattractant receptors belong to a class known as *seven-transmembrane-domain receptors* (also called *serpentine seven receptors* or G *protein–coupled receptors* [GPCRs]); these receptors are composed of a single protein chain whose hydrophobic domains snake across the plasma membrane a total of seven times.[19] Binding of chemoattractants occurs in a pocket on the extra-cellular face of the plasma membrane, at or below the level of the lipid hydrophobic head groups. Receptors for soluble ligands other than chemoattractants have also been identified on neutrophils, including receptors for growth factors, colony-stimulating factors, and cytokines. Growth factor receptors are members of the protein tyrosine kinase receptor family, in which ligand interaction with two identical or related receptors brings them into proximity, causing their cross-phosphorylation and activation. Receptors for a variety of inflammatory stimuli become highly expressed only in mature neutrophils.[20] These receptors include CXC and CC chemokine receptors such as IL-8R-α and -β; CXCR-4 and CCR-1, -2, and -3; receptors for TNF and interferon (IFN)-α and -γ; and interleukin receptors IL1R, IL4R, IL6R, IL10R, and IL17R. Some nonchemoattractant ligands do not directly activate neutrophils but modulate their function. For example, pre-treatment of neutrophils with either insulin or GM-CSF results in amplification of

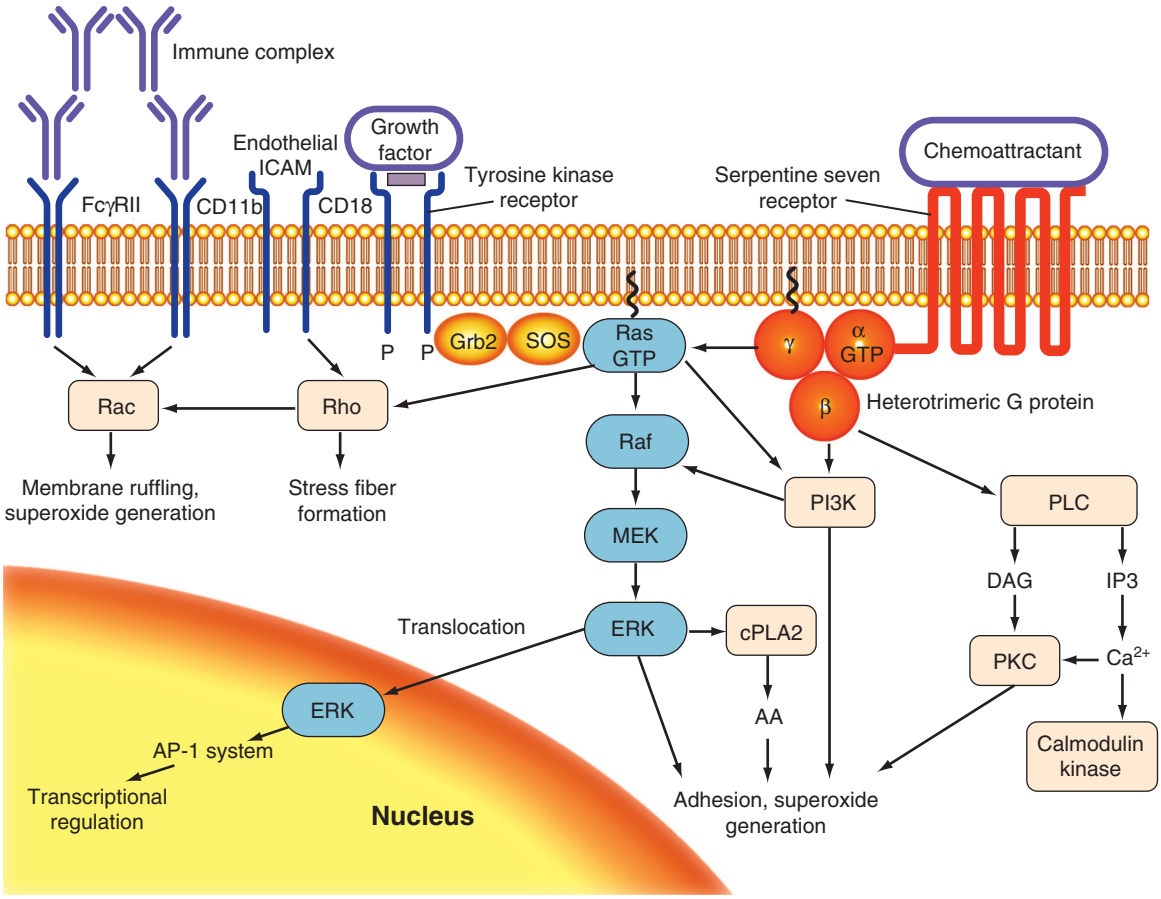

**Figure 11-3** Signaling pathways in neutrophil activation. Engagement of Fc, growth factor, and chemoattractant receptors and adhesion molecules initiate signaling pathways that result in pro-inflammatory neutrophil responses including cytoskeletal and morphologic changes, activation of adhesion molecules and the superoxide generating system (nicotinamide adenine dinucleotide phosphate oxidase), and regulation of transcription. Some of the well-established pathways participating in these responses are illustrated (see text for details). AA, Arachidonic acid; cPLA2, cytosolic phospholipase $A_2$; DAG, diacylglycerol; ERK, extra-cellular–signal regulated kinase; GTP, guanosine triphosphate; ICAM, intercellular adhesion molecule; IP3, inositol 1,4,5-triphosphate; PI3K, phosphatidylinositol 3-kinase; PKC, protein kinase C; PLC, phospholipase C.

subsequent neutrophil responses to chemoattractants, a process referred to as *priming*.

## Guanosine Triphosphate–Binding Proteins

Ligation of seven-transmembrane-domain receptors results in the activation of a class of intra-cellular effectors known as *heterotrimeric guanosine triphosphate (GTP)–binding proteins*, or G proteins. G proteins are comprised of α, β, and γ subunits, and individual G protein types are distinguished by the particular α, β, and γ subunits they employ. In neutrophils, the predominant G proteins are of the $G_i$ family. G protein γ subunits are modified by the addition of prenyl (polyisoprene) and carboxy-terminal methyl groups, which anchor them to the plasma membrane. All G proteins share the capacity, localized to their α subunits, to bind GTP and hydrolyze it to guanosine diphosphate (GDP). G proteins are active when they are GTP bound, but they are inactive in the GDP-bound form. Engagement of the appropriate serpentine-seven receptor promotes the binding of GTP on the α subunit. As a consequence of GTP binding, heterotrimeric G proteins dissociate into α and β/γ components, each with specific effector functions.

A monomeric class of low-molecular-weight (20 to 25 kDa) GTP-binding proteins (LMW-GBPs) is also important in neutrophil signal transduction. Because the first LMW-GBP described was the proto-oncogene Ras, these proteins also are referred to as *Ras-related* or *Ras superfamily proteins*, or simply *small guanosine triphosphatases (GTPases)*. LMW-GBPs combine, in one molecule, the prenyl and methyl modifications of the G protein γ subunit with the GTP-binding capacity of the α subunit.[21] At least four families of LMW-GBP have been described: the Ras family, whose members play roles in activation, as well as cell growth and division; the Rho family, which functions in cytoskeletal rearrangements; and the Rab and Arf families, which are crucial for vesicular and endomembrane trafficking.[22] All four classes of LMW-GBPs are represented in neutrophils.

## Second Messengers

Second messengers are small, diffusible molecules that are generated in response to stimuli and transmit signals from membrane receptors to downstream effector proteins. In the classic model of neutrophil activation, engagement of receptors results in the activation of phospholipase C,

which cleaves phosphatidylinositol triphosphate ($PIP_3$) into diacylglycerol (DAG) and inositol 1,4,5-triphosphate ($IP_3$). DAG and $IP_3$ mediate the influx of cytosolic calcium and the activation of protein kinase C (PKC), respectively. Other phospholipases present in the neutrophil include cytosolic phospholipase $A_2$ (cPLA2), which cleaves phosphatidylcholine and/or ethanolamine to generate arachidonic acid (AA), and phospholipase D, which cleaves phosphatidylcholine into phosphatidic acid and choline.[23] Although many second messengers are implicated in neutrophil activation, others may have inhibitory effects. For example, sphingosine and ceramide inhibit neutrophil phagocytosis.

In addition to lipids, other organic and inorganic second messenger molecules have been characterized. Intracellular concentrations of cyclic adenosine monophosphate (cAMP), a classic second messenger, increase rapidly in neutrophils exposed to both stimuli and inhibitors. In these settings cAMP is likely to provide a negative regulatory (off) signal because direct exposure to cAMP inhibits most neutrophil responses, probably through the activation of protein kinase A (PKA).[18] In contrast, increases in cyclic guanosine monophosphate (cGMP) have a modest enhancing effect on some neutrophil responses. Nitric oxide (NO), an important molecule in the regulation of host defense, is produced in neutrophils at low levels.[24] NO exerts a variety of second messenger effects, including inhibition of reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, actin polymerization, and chemotaxis (discussed later). Conversely, excessive NO production has been implicated in many rheumatic diseases.[25]

## Kinases and Kinase Cascades

Multiple kinases—that is, proteins capable of enzymatically adding phosphate groups to target molecules—contribute to signaling in myeloid and nonmyeloid cells. PKC, which is now understood to be a family of kinases, was among the first kinases implicated in neutrophil activation in response to chemoattractants. The ability of phorbol myristate acetate (PMA), a synthetic activator of PKC, to stimulate neutrophil responses supports a role for PKC in neutrophil activation.[26] Conversely, inhibitors of PKC block stimulation of neutrophil functions.

The mitogen-activated protein kinases (MAPKs) are a family of serine threonine kinases, including the extracellular–signal regulated kinase (ERK), p38, and c-Jun amino terminal kinase (JNK) families. In neutrophils, chemoattractants and other stimuli activate ERK, p38, and JNK, with time courses consistent with neutrophil activation. A role for ERK activation in signaling for both neutrophil superoxide anion ($O_2^-$) and neutrophil adhesion and phagocytosis has been demonstrated.[18,27] Phosphatidylinositol 3–kinase (PI3K) is a set of related enzymes that are found in abundance in neutrophils and primarily catalyze the phosphorylation, not of proteins, but of the 3-position of phosphatidylinositol phospholipids. One of the main bioactive products of PI3K is $PIP_3$. Chemoattractants such as FMLP rapidly activate PI3K in neutrophils, where it participates in diverse neutrophil functions including $O_2^-$ generation, adhesion, and degranulation.[28] PI3K also may regulate neutrophil survival and apoptosis.

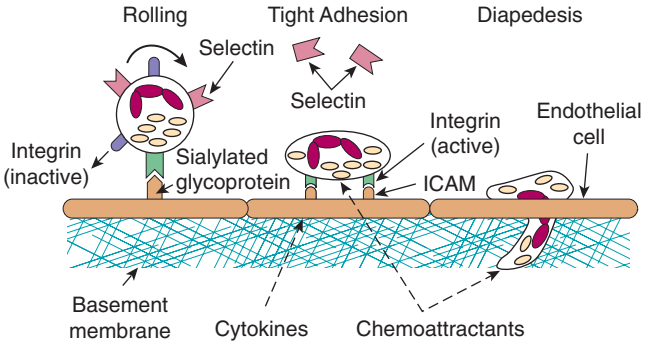

**Figure 11-4** Neutrophil adhesion to the vascular endothelium. *Left,* Rolling. An unstimulated neutrophil adheres with low affinity to the unstimulated endothelium of a postcapillary venule, a process mediated by the interaction of selectins (on neutrophil and endothelium) with sialylated glycoproteins and resulting in the rolling of neutrophils along the vessel wall. *Center,* Tight adhesion. Exposure of the neutrophil to chemoattractants results in activation of integrins (CD11a/CD18, CD11b/CD18); exposure of endothelium to cytokines results in the expression of intercellular adhesion molecules (ICAMs). These molecules interact, resulting in tight adhesion. Concurrently, selectins may be shed from the cell surfaces. *Right,* Diapedesis. A neutrophil undergoes diapedesis, passing across the endothelium and making its way through the basement membrane. Bloodstream neutrophils have the capacity to adhere to and move out of the vasculature in response to tissue signals for inflammation.

# NEUTROPHIL FUNCTION

## Adhesion

One of the earliest, crucial aspects of the inflammatory response is the ability of bloodstream neutrophils to adhere to vascular endothelium preparatory to movement into the tissues (Figure 11-4). Stimulated neutrophils also possess the ability to adhere to each other (homotypic aggregation), which can bring bloodstream neutrophils into proximity with neutrophils already adherent to the vessel or concentrate them at a site of inflammation. Several families of interacting adhesion molecules have been shown to exist on neutrophils and endothelial cells, including selectins, integrins, intercellular adhesion molecules (ICAMs), and sialylated glycoproteins.

### Selectins and Sialylated Glycoproteins

The selectin family includes three related molecules (L-selectin on leukocytes, E-selectin on endothelial cells, and P-selectin on activated platelets and endothelial cells). Selectins share a common structure of two or more complement regulatory domains, an epidermal growth factor–like domain, and a lectin domain. Each selectin binds to a specific sialylated glycoprotein on the surface of its interacting cell: E-selectin binds to the sialyl Lewis$^x$ antigen on neutrophils, P-selectin binds P-selectin glycoprotein-1 (PSGL-1) on neutrophils, and L-selectin binds PSGL-1 and glycosylation-dependent cell adhesion molecule-1 (GlyCAM-1) on the endothelium. Selectin/sialylated glycoprotein interactions are of low affinity and transient, and leukocytes therefore repetitively bind to, and release from, the endothelial surface. The result is a pool of bloodstream neutrophils that is, at any given time, loosely marginated to the vascular surface and moving along it slowly

in a rolling, tumbleweed-like motion. Exposure of neutrophils and endothelium to appropriate stimuli (e.g., adrenergic discharge and corticosteroids) leads to shedding of selectins and neutrophil release (demargination), with apparent increases in the peripheral neutrophil count.

### Integrins and Intercellular Adhesion Molecules

The integrins are a large family of heterodimeric molecules generated by various combinations of α and β chains. Like the selectins, integrins require divalent cations ($Ca^{2+}$ or $Mg^{2+}$ or both) to engage their ligands. Neutrophils express three $\beta_2$-type integrins, each constructed from a distinct α subcomponent (CD11a, CD11b, or CD11c) and a common $\beta_2$ chain (CD18). Integrins primarily use ICAMs as their counterligands. CD11b/CD18 (also called *Mac-1* or *CR3*) binds to fibrinogen, factor X, heparin, and the complement component iC3b in addition to ICAMs; it is most strongly implicated in neutrophil/endothelial and neutrophil/neutrophil interactions. In contrast to the selectins, neutrophil CD11b/CD18 is constitutively expressed but inactive; stimulation of neutrophils results in changes in the CD11b/CD18 activation state and increases its affinity for ICAMs and other ligands.[29] Stimulation of endothelium with cytokines such as IL-1β results in increased expression of ICAM-1 and ICAM-2, providing a coordinate mechanism for the regulation of adhesion. In contrast to selectin-mediated adhesion, integrin/ICAM interactions are high affinity and persistent. Stimulation of rolling neutrophils therefore results in their tight adhesion to vessel walls and constitutes the first committed step in the movement of neutrophils into tissues. Additionally, engagement of integrins by their counterligands sends signals into the cell ("outside in" signaling) that regulate selective cell responses such as cytoskeletal reorganization, oxidant production, and degranulation. Outside-in signaling through CD11b/CD18 also coordinates with signaling through Fc receptor FcγRIII to regulate a number of different functions, including phagocytosis of particles opsonized by immunoglobulin (Ig)G and the complement component iC3b, along with neutrophil-dependent adhesion in immune complex–mediated vascular inflammation.[30] Cross-talk between neutrophils and endothelial cells has been shown to be a CD11b/CD18-dependent event: cross-linking of CD18 on neutrophils leads to increased endothelial permeability, probably through the release of neutrophil proteases.[31]

The function of CD11a/CD18 (also known as lymphocyte function–associated antigen [LFA]-1) on neutrophils has been controversial, but accumulating data indicate that this molecule may be necessary for neutrophil adhesion and emigration.[32] During neutrophil rolling on inflamed endothelium, neutrophil engagement by PSGL-1 leads to CD11a/CD18 activation, which in turn contributes to neutrophil arrest.[33] The function of CD11c/CD18 in neutrophils remains less clear.

## Diapedesis and Chemotaxis

### Diapedesis

The mechanism by which neutrophils pass through blood vessels *(diapedesis)* is not fully established. One report suggests a model in which neutrophils pass directly through pores generated within the endothelial cells themselves, but neutrophils are more generally thought to pass between endothelial cells by disrupting cell-cell junctions (Figure 11-5).[34] Diapedesis requires homotypic interactions between adhesion molecules found on neutrophils and endothelial cells known as *platelet–endothelial cell adhesion molecules* (PECAMs). These molecules are concentrated at endothelial cell junctions, and antibodies that block PECAM inhibit transmigration in vitro by limiting neutrophils to the apical surface of the endothelium. Transmigrating neutrophils undergo upregulation of α6β1, an integrin that mediates binding to laminin (a key component of the perivascular basement membrane). Antibodies to α6β1 generally block neutrophil transmigration but fail to do so in a PECAM knockout mouse, implicating α6β1/PECAM as crucial to the passage of neutrophils out of the vasculature.[35] CD47, otherwise known as *integrin-associated protein*, and CD99, expressed on neutrophils and endothelial junctions, have also been implicated in neutrophil passage through the endothelium.

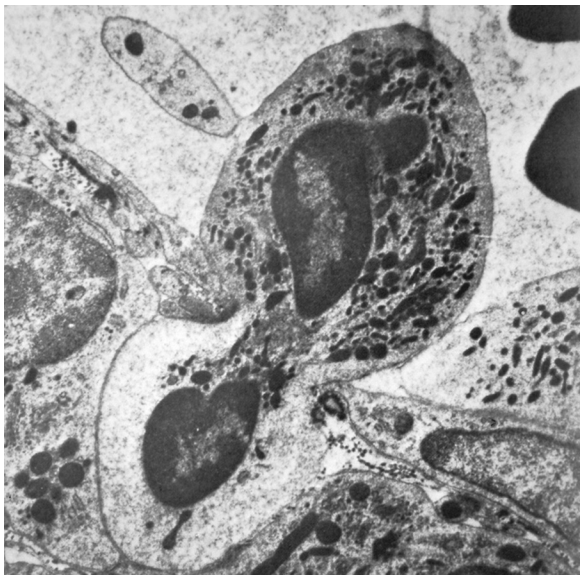

**Figure 11-5** Neutrophil diapedesis through the vascular endothelium. A neutrophil passaging between, or through, one or more endothelial cells is illustrated. The characteristic neutrophil multilobed nucleus and multiple granule types are visible. The leading edge of the neutrophil, passing through the endothelium, is relatively devoid of granule contents, suggesting that it represents the formation of a specialized structure for diapedesis, including the formation of F-actin cytoskeleton.

Once beyond the endothelium, neutrophils typically pause before traversing the basement membrane (basal lamina). Classic studies by Huber and Weiss suggest that neutrophils pass through the basement membrane via active disruption of its patency, without utilization of known proteases or oxygen radicals.[36] The disruptions are rapidly repaired by an unknown mechanism likely involving the endothelium.

### Chemotaxis

Chemotaxis in the direction of a molecular gradient is achieved by the extension of membrane ruffles (lamellipodia), followed by anchorage of the ruffles to the substrate

and withdrawal of the trailing edge of the cell in the direction of movement. These changes are accomplished primarily through rearrangement of the actin cytoskeleton after sensing chemotactic gradients that signal through GPCRs and PI3K. Actin is a 41 kDa protein that exists as a soluble, globular monomeric form (G-actin) and as an insoluble linear polymer (F-actin). F-actin may be assembled (extended) at one end (the barbed end) and disassembled at the other, under the control of regulatory molecules. During chemotaxis, F-actin formation and extension is concentrated at the leading edge of the neutrophil, permitting extension of the cell membrane (Figure 11-5). Chemoattractant receptors also concentrate at the leading edge, defining the cell's directional response to the gradient (the headlight phenomenon). As the neutrophil moves along, receptors that were formerly at the leading edge are swept to the tail and internalized.

## Phagocytosis and Degranulation

### Phagocytosis

Neutrophil phagocytosis of an encountered bacterium or other particle requires direct contact. Phagocytosis can be activated by direct neutrophil recognition of pathogen-associated molecular patterns (PAMPs), which are small molecule motifs found on or in bacteria or viruses (but not typically mammalian cells). PAMPs are recognized by Toll-like receptors (TLRs)[37] and other pattern recognition receptors (PRRs). Human neutrophils express all TLRs except for TLR3, and TLR activation stimulates human neutrophil phagocytosis by promoting structural and conformational changes.[38] However, neutrophils are generally poor at phagocytosing unmodified targets, particularly encapsulated bacteria. Phagocytosis is greatly enhanced by opsonization (from the Greek, "to prepare for the table"), that is, the modification of a target via its decoration with immunoglobulin, complement components, or both (Figure 11-6).

Neutrophils express two families of receptors for the Fc portion of complexed or aggregated IgG: low-affinity FcγRIIa and high-affinity FcγRIIIb. During some infections, or after in vitro stimulation with interferon or G-CSF, neutrophils also express the high-affinity receptor FcγRI, which binds monomeric IgG. FcγRIIa binds subclasses of IgG with varying efficiency depending on a polymorphism at amino acid position 131. FcγRIIIb polymorphisms of neutrophil antigens NA1 and NA2 also determine binding to IgG subclasses. Persons homozygous for the NA2 allele have a lower capacity to mediate phagocytosis than do persons homozygous for the NA1 allele. These differences have important implications for rheumatic diseases in which immune complexes play an important role.

Phagocytosis is an active process involving extension of the neutrophil membrane (filopodia and lamellipodia formation) and invagination of the neutrophil at the locus of the target. Engagement of FcγR and complement receptors results in the activation of different signaling pathways that play distinct roles in phagocytosis.[39] Whereas engagement of CR3 (CD11b/CD18) results in actin stress fiber formation and invagination, engagement of FcγRII results primarily in extension of membranes out from and around the target. Signaling by these receptors depends on the activation of distinct members of the Rho family of LMW-GBPs.

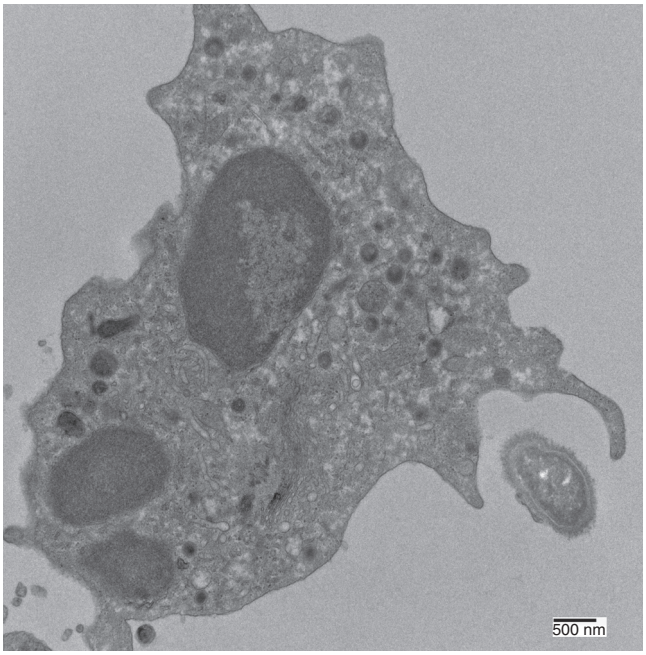

**Figure 11-6** A neutrophil engulfing bacteria. Neutrophils can internalize and kill many microbes, with each phagocytic event resulting in the formation of a phagosome into which reactive oxygen species and hydrolytic enzymes are secreted. This transmission electron micrograph shows the precise moment in which a bacterium is being phagocytosed by a neutrophil. *(Courtesy K.A. Zarember, D.E. Greenberg, and K. Nagashima, Laboratory of Host Defenses, National Institute of Allergy and Infectious Diseases, National Institutes of Health.)*

### Degranulation

Upon engaging a target, neutrophils degranulate, a term reflecting two possible and distinct events. Vesicles can fuse with the plasma membrane, spilling their contents into the extra-cellular space (see Figure 11-1), or they can fuse with the phagocytic vacuole to form a phagolysosome. The former type of degranulation is regulated differentially from the latter and favors mobilization of lighter granules in response to stimuli (secretory vesicles > gelatinase granules > specific granules > azurophilic granules). In the latter type of degranulation (phagolysosome formation), the preferential fusion of azurophilic granules with the phagocytic vacuole results in the delivery of proteolytic proenzymes, MPO, and antibacterial proteins to the site of an ingested bacterium. Fusion of specific granules with the phagocytic vacuole permits the delivery of collagenase, activation of azurophilic granule enzymes, and the appropriate localization of cytochrome $b_{558}$, a requisite for NADPH oxidase (discussed later). Containment of potentially toxic substrates within the phagolysosome keeps host tissue damage and neutrophil autodestruction in check. However, control of granule content is imperfect and toxic molecules may still spill into the extra-cellular milieu. As discussed subsequently, however, in several of the rheumatic diseases, neutrophil activation plays an important role in abetting inflammation and host tissue damage.

## Respiratory Burst

In addition to the proteases and other antibacterial proteins contained in their granules, neutrophils have the capacity to kill bacteria through the generation of toxic oxygen metabolites such as NO, $O_2^-$, and $H_2O_2$. This process, mediated by the NADPH oxidase system and frequently referred to as the *oxidative or respiratory burst*, is extremely potent and requires tight regulation to prevent neutrophil autodestruction.[40] The central component of NADPH oxidase is cytochrome $b_{558}$, which is localized to the membranes of specific granules and consists of two subunits: a 22 kDa component (gp22$^{phox}$, for *ph*agocyte *ox*idase) and a 91 kDa component (gp91$^{phox}$). This cytochrome lacks independent activity, however, and three cytosolic proteins are also required for oxidase activation: a 47 kDa and a 67 kDa component (p47$^{phox}$ and p67$^{phox}$) and a LMW-GBP, p21$^{rac}$.[41] On neutrophil stimulation, the p47$^{phox}$ and p67$^{phox}$ components translocate to the membranes to form an active complex with the cytochrome (Figure 11-7).[41] Although p21$^{rac}$ also translocates in response to stimuli and appears to be necessary for oxidase system activity, the significance of its translocation is more controversial.[42] A fifth protein, p40$^{phox}$, associates with p47/p67, regulates the oxidase system, and plays a role in phagocytosis-induced superoxide production.[43]

When assembled and activated, the NADPH oxidase transfers electrons from NADPH to generate $O_2^-$:

$$2O_2 + NADPH \xrightarrow{\text{NADPH Oxidase}} 2O_2^- + NADP^+ + H^+$$

A subsequent, spontaneous dismutase reaction rapidly produces $H_2O_2$:

$$2O_2^- + 2H^+ \rightarrow H_2O_2 + O_2$$

Although $O_2^-$ and $H_2O_2$ can kill organisms in vitro, they are short-lived and probably do not account for most of the bacterial killing capacity of the system under normal circumstances Indeed, many bacteria possess catalase, an enzyme that degrades $H_2O_2$. Instead, the production of $H_2O_2$ within the same space into which MPO has been released permits the generation of large quantities of hypochlorous acid, a powerful oxidant with potent killing capacity. Hypochlorous acid can interact further with proteins to form chloramines, which are less potent but longer-lived oxidants. Neutrophil oxidant production plays a key role in the body's defense against microorganisms.

The current view that oxidant production, via the production of hypochlorous acid by MPO, is the neutrophil's most powerful tool against microbes has been challenged, however. Mice lacking either NADPH oxidase or elastase and cathepsin G are susceptible to infection, implying that both arms of defense—oxidant production and protease-mediated microbial destruction—are equally crucial. Moreover, superoxide production in phagocytic vacuoles may indirectly promote protease function by causing the vacuolar pH to rise (secondary to the consumption of protons necessary to make $H_2O_2$), which, in turn, causes an influx of $K^+$. The resulting increase in ionicity liberates cationic proteases from the anionic proteoglycan matrix, freeing them to kill bacteria. In this new model, oxidants are not primarily destructive to microbes, but rather are necessary to assist proteolytic damage.[44]

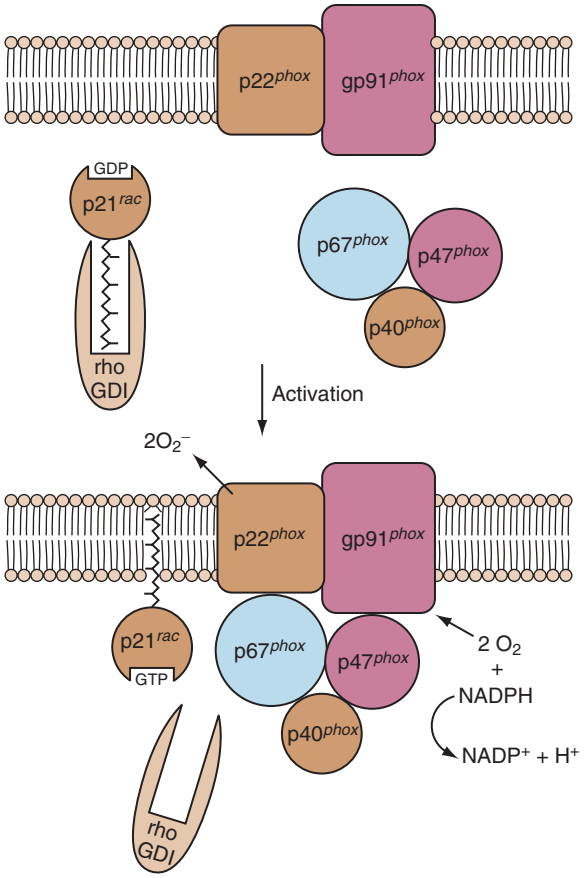

**Figure 11-7** Assembly of the neutrophil nicotinamide adenine dinucleotide phosphate (NADPH) oxidase system. *Top,* Basic components of the NADPH oxidase as they are distributed in a resting state. The cytochrome $b_{558}$, composed of the two subunits gp91$^{phox}$ and p22$^{phox}$, are membrane associated, whereas p47$^{phox}$, p67$^{phox}$, and the more recently identified p40$^{phox}$ exist as a complex in the cytoplasm. p21$^{rac}$ in an inactive, guanosine diphosphate (GDP)-bound form also resides in the cytoplasm, in association with a chaperone (Rho-GDI) that sheaths its hydrophobic tail to permit solubility. *Bottom,* Activation of the neutrophil leads to translocation of the cytosolic components of the oxidase to the neutrophil membrane, where they form an active complex with the cytochrome, resulting in the generation of oxygen. The potentially damaging oxidase system is carefully regulated through the segregation and assembly of its component parts.

## Nonphagocytic Mechanisms of Neutrophil Action

Recently discovered nonphagocytic mechanisms of neutrophil-mediated bacterial killing further augment host defense.

### Neutrophil Extra-cellular Traps

Neutrophil extra-cellular traps, or NETs, are extra-cellular meshes composed of chromatin and neutrophil granular proteins (Figure 11-8).[45] In some circumstances NETs are released upon cellular activation. They entrap bacteria while simultaneously providing a scaffold to promote high local concentrations of anti-microbial components, thus killing microbes extra-cellularly. NET formation can be suicidal to neutrophils, leading to chromatin decondensation, nuclear swelling, and membrane perforation (suicidal NETosis).[46] Chromatin decondensation depends on histone

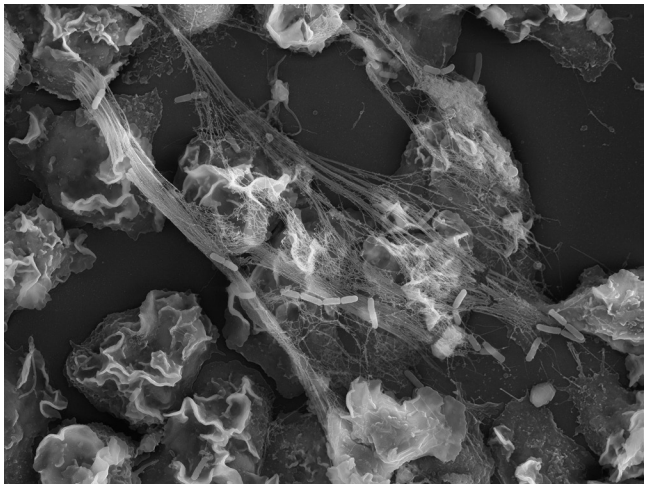

**Figure 11-8** Neutrophil extra-cellular traps (NETs). NETs are complex extra-cellular structures that are composed of chromatin, with specific proteins from the neutrophilic granules attached. NETs can trap Gram-negative bacteria, Gram-positive bacteria, and fungi. A scanning electron micrograph shows stimulated neutrophils forming NETs to trap *Shigella flexneri. (Courtesy V. Brinkmann and A. Zychlinsky, Max Planck Institute for Infection.)*

hypercitrullination catalyzed by peptidylarginine deiminase 4, as well as neutrophil elastase, which digests nucleosomal histones.[47,48] MPO binding of chromatin enhances nuclear decondensation and may also thereby promote suicidal NETosis.[49] However, not all NETosis leads to neutrophil destruction. In some cases neutrophils undergo "vital NETosis" in which they lose their nuclear material but retain the ability to chemotax and phagocytose microorganisms.[50] NETosis is also driven partly by reactive oxygen species, because neutrophils in which oxidant production is blocked are unable to undergo NETosis.[51,52]

## Microparticles

Neutrophil-derived microparticles are emancipated cytosol-entrapping vesicles of neutrophil plasma membrane. Like NETs, microparticles are previously unappreciated propagators of neutrophil-mediated outcomes (Figure 11-9). During activation, neutrophils release these heterogeneous vesicles, which range in diameter between 100 and 1000 nm and express surface markers of their parent cells. Microparticles can bind to target cells (including endothelial cells) in a receptor-dependent manner and, in so doing, transfer parent

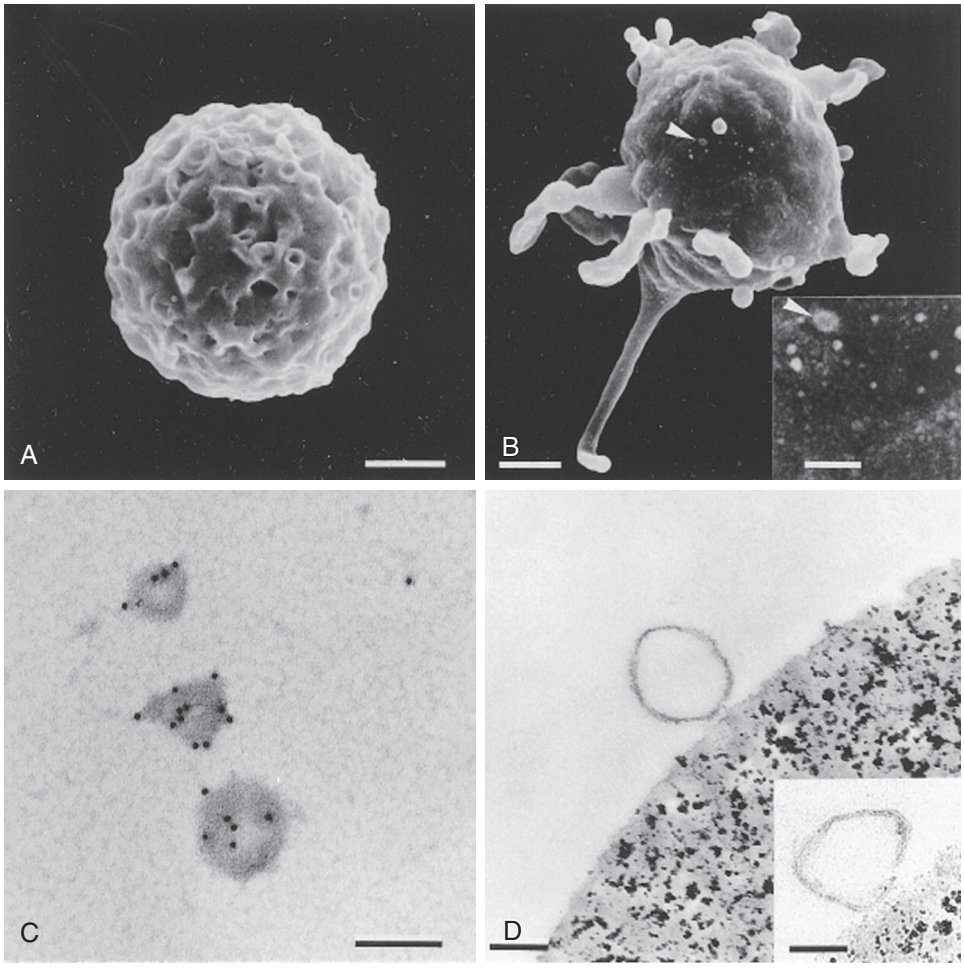

**Figure 11-9** Neutrophil microparticles. **A,** Scanning electron micrograph of a resting neutrophil (scale bar: 1.5 μm). **B,** Scanning electron micrograph of a stimulated neutrophil 0.1 μM N-formyl-methionyl-leucyl-phenylalanine (FMLP). cell messenger RNA (mRNA) and microRNA (miRNA) to drive transcellular responses. Microparticle numbers increase in sepsis, as well as vascular disease, and they also appear to play a significant role in infection-mediated thrombosis.[53-56]

## Neutrophil Production of Pro-inflammatory Mediators

### Arachidonic Acid Metabolites

The capacity of stimulated neutrophils to liberate AA from membranes has implications for acute inflammation. Although AA has intrinsic chemoattractant and neutrophil-stimulatory properties, its metabolites are more crucial to inflammatory effects.[27,57,58] Best recognized among these metabolites are the leukotrienes (LTs). Neutrophils can produce $LTB_4$, a highly potent mediator for the chemoattraction of other neutrophils.[57] Intermediates of LT production (e.g., 5-hydroxyeicosatetraenoic acid) also are produced by neutrophils and may have stimulatory properties.[27]

The cyclo-oxygenase (COX) (endoperoxide synthase) pathway is the other major pathway of AA metabolism. AA metabolized by COX is converted into prostaglandin H, which undergoes further cell type-specific conversion to a variety of other prostaglandins.[59] The prostaglandin of most relevance to inflammation is prostaglandin $(PG)E_2$, whose numerous pro-inflammatory effects include increased vasodilation, vascular permeability, and pain. Interestingly, the direct effects of $PGE_2$ on neutrophils are largely inhibitory, probably through elevations of intra-cellular cAMP.[60] Although resting neutrophils exhibit little COX activity, persistent activation results in upregulation of COX-2, suggesting that neutrophils may contribute $PGE_2$ to both the inflammatory brew and the downregulation of their own activity.

### Cytokine Production

Although the relative amount of cytokine production by neutrophils is small, the large numbers of neutrophils present in infected or inflammatory sites suggest that overall neutrophil cytokine production may play a role in recruiting additional neutrophils to the target area. Cytokines produced by neutrophils include IL-8, IL-12, MIP-1α and β (CCL3 and CCL4), growth-related oncogene-α (GRO-α), oncostatin M, monocyte chemotactic protein (MCP)-1, and TGF-β. Multiple lines of investigation suggest that neutrophils may also be a source for IL-17, a potent cytokine that can amplify neutrophil migration and recruitment.[61]

Neutrophils do not produce IL-1β, TNF, or IL-6, the classical products of macrophages and synovial cells.[62] The transcriptional program of terminally differentiated neutrophils requires a selective combination of stimulants for the production of chemokines. In the presence of lipopolysaccharide, TNF drives neutrophil production of IL-8, GRO-α, and MIP-1, whereas IFN-γ drives CXCL9 and 10.[63] Other neutrophil-derived molecules have been identified as bridging factors between innate and adaptive immunity. Activated neutrophils release both B-lymphocyte stimulator (BLyS) and TNF-related apoptosis-inducing ligand (TRAIL).[64,65] Whereas BLyS stimulates B cell proliferation (through the TNF family receptors BAFF-R, TACI, and BCMA), TRAIL induces anti-tumor T cell effects and apoptosis.

TGF-β is a neutrophil chemoattractant at femtomolar concentrations, and its recruitment of neutrophils into an inflammatory space may lead to additional neutrophil cytokine production, including further production of TGF-β.[66] TGF-β also has potent anti-inflammatory effects and blocks neutrophil degranulation in response to lipopolysaccharide (LPS), FMLP, and TLR ligands.[16,67]

## Role of Neutrophils in Thrombosis

Recent evidence indicates that neutrophils play a key role in the activation of platelets and thrombin, underlining the interaction between inflammation and thrombosis. Neutrophils that accumulate at sites of inflammation do so in concert with aggregating platelets and further enhance platelet aggregation (Figure 11-10). Platelet-neutrophil complexes are elevated in patients with systemic lupus erythematosus and rheumatoid arthritis (RA), likely as a result of neutrophil activation.[68] On the other hand, in the setting of vascular injury and endothelial damage, platelets activated in response to exposed collagen express P-selectin, promoting neutrophil-platelet associations via neutrophil PSGL-1 counter-receptors. Subsequent activation of neutrophils leads to firmer bonds as a result of integrin CD11b/CD18 adhesion molecule activation.[69]

Neutrophil-platelet interactions result in surface expression of tissue factor that can initiate the coagulation cascade.[70] Neutrophil NETs can also play roles in promoting clotting, including disseminated intravascular coagulation. In those cases, extruded neutrophil chromatin serves as a platform for the extra-cellular co-localization of neutrophil elastase and the anti-thrombotic tissue factor pathway inhibitor (TFPI). Inactivation of TFPI by elastase then permits clotting to proceed.[71] In a flow restriction murine model of deep vein thrombosis, NETs were present in thrombi, and mice treated with deoxyribonuclease (DNAse) or rendered neutropenic were protected against clot formation.[72]

## Resolution of Neutrophil Infiltration

Inflammatory responses must eventually be resolved to avoid excessive tissue damage and initiate the healing process. Resolution of inflammation is an active and carefully regulated process. Pro-resolution signals include lipid derivatives (e.g., resolvins and lipoxins), annexin A1 and chemerin-derived peptides, and certain chemokines and cytokines.

### Resolvins

Resolvins differ according to the lipid from which they are derived. Resolvin E1 is produced from eicosapentaenoic acid and inhibits monocytes, macrophages, and dendritic cells (DCs), as well as neutrophils.[73,74] Resolvin D derives from docosahexaenoic acid and is also a potent inhibitor of neutrophil diapedesis and migration.[75] Maresin-1 (macrophage mediator in resolving inflammation-1) has properties similar to the D-resolvins.[76] Some prostaglandins such as $15d\text{-}PGJ_2$ also have anti-inflammatory properties.[77]

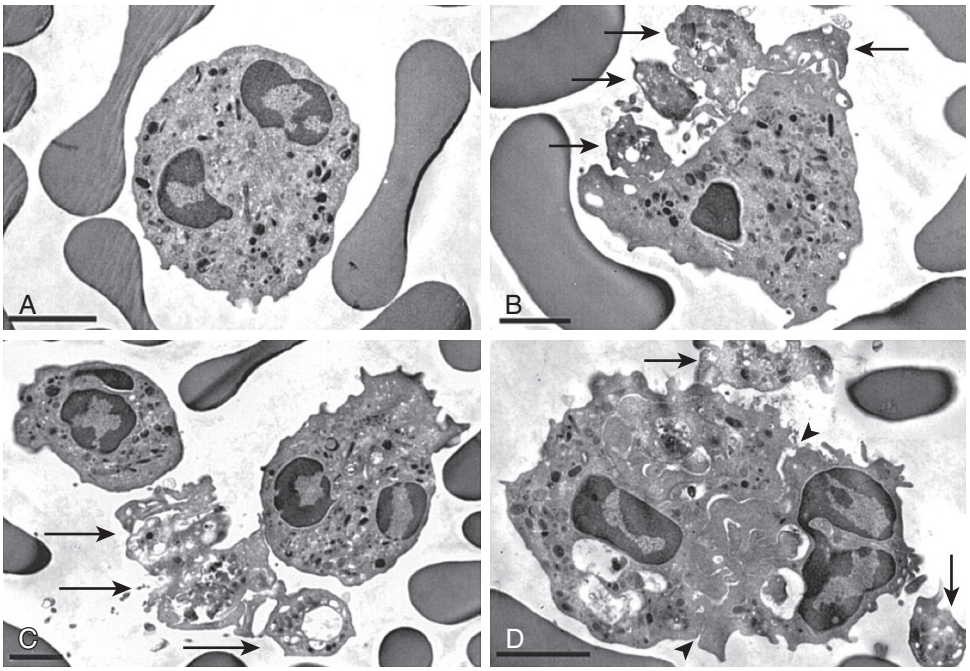

**Figure 11-10** Neutrophil-platelet interactions and neutrophil-neutrophil aggregation in blood specimens subjected to hydrodynamic shear, examined by transmission electron micrograph. **A,** A single neutrophil with few to no adherent platelets appears round (unactivated). **B,** A neutrophil bound to four platelets undergoes a shape change (i.e., it is activated by platelet contact). **C** and **D,** Neutrophil aggregates observed with platelets forming bridges between neutrophils **(C)** and on the periphery of homotypically aggregating neutrophils **(D)**. ### Lipoxins

The lipoxins are derived from AA and are potent anti-inflammatory molecules.[57] Lipoxin synthesis requires coordinated activity of neutrophil 5-lipoxygenase and a related enzyme (either 12-lipoxygenase or 15-lipoxygenase) from another cell type—either platelets or endothelial cells (Figure 11-11).[78] In contrast to LTs and prostaglandins, lipoxins are anti-inflammatory, suggesting that the accumulation of a mixed population of inflammatory cells may redirect arachidonate metabolism into the synthesis of anti-inflammatory molecules to promote the resolution of inflammation.[79] In some cases, apoptotic neutrophils at sites of inflammation are taken up by resident macrophages, promoting lipoxin A4 production.[80] Aspirin stimulates the generation of biologically active epilipoxins, suggesting a previously unappreciated mechanism for its anti-inflammatory action.[81]

### Other Inflammation-Resolving Molecules

After neutrophil activation, annexin A1 (lipocortin) is released in response to chemoattractants, downregulating transmigration and promoting neutrophil apoptosis and clearance.[82] Similar activities have been attributed to chemerin-derived peptides.[83] Activated neutrophils also produce IL-1 receptor antagonist (IL-1ra).[84] The efficacy of recombinant IL-1ra (anakinra) therapy in autoinflammatory diseases emphasizes its clinical importance in suppressing inflammation. An MMP-mediated mechanism of inflammatory resolution has also been identified. Macrophage-derived MMPs, such as MMP-1, MMP-3, and

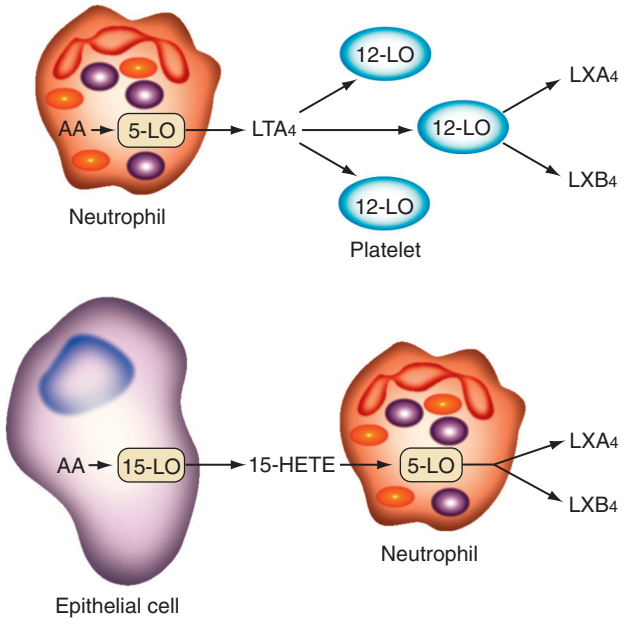

**Figure 11-11** Generation of the anti-inflammatory lipoxins $A_4$ and $B_4$ depends on the interaction between two different classes of inflammatory cells. *Top,* Lipoxin generation by neutrophils and platelets. Arachidonic acid (AA) generated by activated neutrophils is converted by neutrophil 5-lipoxygenase (5-LO) into leukotriene $A_4$ ($LTA_4$). $LTA_4$ may be converted by 12-LO in nearby platelets into lipoxin $A_4$ ($LXA_4$) and lipoxin $B_4$ ($LXB_4$). *Bottom,* Lipoxin generation by epithelial cells and neutrophils. AA generated by epithelial cells may be converted by 15-LO into 15-hydroxyeicosatetraenoic acid (15-HETE). In the setting of inflammation, 5-LO from adjacent neutrophils subsequently may convert 15-HETE into $LXA_4$ and $LXB_4$.

MMP-12, cleave CXC-chemokines, provoke the loss of their neutrophil-recruiting activity, and dampen the influx of cells.[85]

### Role of Apoptotic Neutrophils in Resolving Inflammation

Apoptotic neutrophils can inhibit live neutrophil chemotaxis and migration via release of lactoferrin and annexin A1.[86] Apoptotic neutrophils can also suppress granulopoiesis by inhibiting the pro-inflammatory consequences of IL-17/IL-23 axis activation. In this model, macrophages and DCs produce IL-23 at the site of insult, which in turn promotes IL-17 production by T cells (T helper [Th]17, γδ T cells, and natural killer [NK] T cells). IL-17 is a promoter of G-CSF production and a powerful neutrophil chemoattractant. Recruited neutrophils undergo apoptosis and are phagocytosed by macrophages, resulting in a decrease of IL-23. This decrease is followed by a reduction in IL-17 and G-CSF production, which downregulates granulopoiesis.[87]

An intriguing mechanism through which neutrophils might downregulate the action of protein inflammatory mediators has been defined. Apoptotic neutrophils (present during the resolving phase of inflammation) show increased expression of the chemokine receptor CCR5 on their surface (mediated by D and E resolvins), and this receptor can scavenge and reduce the soluble concentration of chemokines such as CCL3 and CCL5. These data emphasize again that neutrophils are not only inflammatory cells but may also play a direct role in the subsequent resolution of inflammation.[88]

## HERITABLE DISORDERS OF NEUTROPHIL FUNCTION

A variety of acquired conditions result in neutrophil dysfunction and/or depletion, including malignancies (myeloid leukemias), metabolic abnormalities (diabetes), and drugs (e.g., corticosteroids and chemotherapy). In addition, rare congenital disorders of neutrophils have been identified (Table 11-2). In general, patients with congenital impaired neutrophil function are prone to infection by bacteria (predominantly *Staphylococcus aureus*, *Pseudomonas* species, *Burkholderia*) and fungi (e.g., *Aspergillus* and *Candida*), but not viruses and parasites. The major sites of infection include skin, mucous membranes, and lungs, but any site may be affected, and spreading abscesses are common. Most of these diseases are potentially life threatening in the absence of available effective therapy.

### Diseases of Diminished Neutrophil Number

Severe congenital neutropenia (SCN, Kostmann's syndrome) results from marrow arrest of bone marrow myelopoiesis and leads to neutrophil counts persistently less than $0.5 \times 10^9$ cells/L. Monogenic autosomal dominant, autosomal recessive, sporadic, and polygenic subtypes have been identified.[89,90] Patients are prone from early infancy to severe bacterial infections including omphalitis, pneumonia, otitis, gingivitis, and perirectal infections. Because of the lack of acute inflammation, infections tend to spread extensively before being noted, and the mortality rate is high. Therapy consists of antibiotics and long-term treatment with recombinant G-CSF, which may help maintain normal or near-normal neutrophil counts. Patients with SCN are also at risk for acute myeloid leukemia (AML) and myelodysplastic syndrome, particularly those who respond poorly to G-CSF.[91] A milder form of neutropenia (benign congenital neutropenia) with higher neutrophil counts and fewer infections has also been observed. Another variant is cyclic neutropenia, which causes transient, recurrent neutropenia on a 21-day cycle. Studies suggest that defects in neutrophil elastase affect neutrophil survival in the marrow and may be responsible for severe congenital and cyclic neutropenia.[92] At least 52 different mutations in the *ELANE* gene, which encodes neutrophil elastase, have been described as the cause in around half of the patients.[93] Mutations in *HAX1* and glucose-6-phosphatase catalytic subunit 3 *(G6PC3)* genes account for a smaller proportion of cases of SCN. Other, less frequent deficiencies include X-linked neutropenia—caused by constitutively active mutations of the *WAS* gene—and defects in several myeloid transcription factors.

### Leukocyte Adhesion Deficiencies

Leukocyte adhesion disorders arise from defects in cell adhesion to extra-cellular matrix and vascular endothelium. Three distinct entities have been described in humans. Leukocyte adhesion deficiency type 1 (LAD1) results from an autosomal recessive defect in ITGB2, which encodes the CD18 chain of β2 integrins. Consequently, neutrophil β2 integrins fail to form, and bloodstream neutrophils are unable to adhere firmly to vascular endothelium and transmigrate to sites of infection.[94] Phagocytosis is also impaired. The clinical picture is similar to that of the neutropenias, with recurrent life-threatening infections. Peripheral neutrophil counts are typically elevated, however, reflecting the intravascular accumulation of cells in the face of their inability to exit the vessels. Complete LAD1 manifests in infancy and is characterized by omphalitis, recurrent life-threatening bacterial and fungal infections, gingivitis, and delayed wound healing. Absence of pus at infection sites is a hallmark of LAD1. Bone marrow transplantation is the only curative therapy. LAD2 results from an autosomal recessive defect in the glycosylation of sialyl Lewis$^x$ (SLex or CD15s), the neutrophil counter-ligand for endothelial selectins. Patients with LAD2 have neutrophils that are unable to roll along the endothelium and have symptoms similar to LAD1 but may also have mental retardation, short stature, distinctive facies, and the Bombay (hh) blood type.[95] A third variant, LAD3, has been described in which leukocytes have normal populations of surface integrins but lack the ability to signal these molecules into an active state.[96] Because integrin activation in this condition is also deficient in platelets, patients with LAD3 are at increased risk for infection and bleeding.

### Granule Defects

Chédiak-Higashi syndrome is an autosomal recessive disorder in which granule subtypes—in neutrophils, lymphocytes, melanocytes, Schwann cells, and others—undergo disordered fusion, resulting in giant, dysfunctional granules. The cause seems to be related to a defect in the gene for

**TABLE 11-2** Heritable Disorders of Neutrophil Function

| Disorder | Defect | Inheritance | Presentation | Therapy | Typical Prognosis |
|---|---|---|---|---|---|
| **Neutropenia** | | | | | |
| Severe congenital neutropenia (Kostmann's syndrome) | Maturation arrest (<0.5 × $10^9$ PMN/L) | AR (HAX1 mutations) | Bacterial infections (omphalitis, abscesses, gingivitis, UTIs) | RhG-CSF | Improved with treatment |
| Benign congenital neutropenia | Multiple etiologies (0.2-2 × $10^9$ PMN/L) | Variable | Mild infections | None | Good |
| Cyclic neutropenia | Stem cell defect, elastase gene deficiency (nadir every 21 days) | AD (ELA2 mutations) | Infection during nadirs | RhG-CSF | Improved with treatment |
| **Adhesion Deficiency** | | | | | |
| Leukocyte adhesion deficiency type 1 | Absent or abnormal CD18; deficiency in β2-integrin chain of leukocyte adhesion molecules | AR | Leukocytosis; recurrent infections (skin mucous, membranes, gastrointestinal tract) | Marrow transplant | Fair-poor |
| Leukocyte adhesion deficiency type 2 | Absent sialyl-Lewis$^x$ | AR | Neutrophilia; infection; retardation, short stature | | Poor |
| Leukocyte adhesion deficiency type 3 | Impaired activation of Rap1 GTPase | AR | Leukocytosis; recurrent infections; bleeding tendency | | Poor |
| **Chemotaxis Deficiency** | | | | | |
| Hyper-IgE syndrome | Chemotaxis defect | AD | Eczema; recurrent infections; elevated serum IgE levels | Skin care; antibiotics | Good |
| **Granule Disorders** | | | | | |
| Chédiak-Higashi syndrome | Defective lysosomal trafficking regulator gene | AR | Albinism; infection | Marrow transplant; antibiotics | Poor |
| Specific granule deficiency | Abnormal/reduced specific and azurophilic granules (lactoferrin deficiency) | AR? | Infection of skin, mucous membranes, lungs | | Fair-good |
| Myeloperoxidase deficiency | Myeloperoxidase absent | Variable (mostly AR) | None | Transfusion of HLA-identical leukocytes if severe | Excellent |
| p14 deficiency | Defective endosomal adapter protein gene | Recessive | Albinism; infection; short stature | None known to date | ? |
| **Oxidase Defects** | | | | | |
| Chronic granulomatous disease (multiple types) | gp91$^{phox}$ absent<br>p22$^{phox}$ absent<br>p47$^{phox}$ absent<br>p67$^{phox}$ absent<br>p40$^{phox}$ absent | X-linked 50%<br>AR 5%<br>AR 35%<br>AR 5%<br>AR 5% | Early childhood infections, especially skin and mucous membranes, abscesses | Interferon-γ | Improved with treatment |

AD, Autosomal, dominant; AR, autosomal, recessive; GTPase, guanosine triphosphatase; HLA, human leukocyte antigen; IgE, immunoglobulin E; PMN, polymorphonuclear neutrophil; RhG-CSF, recombinant human granulocyte colony-stimulating factor; UTIs, urinary tract infections.

lysosomal transport regulator (Lyst or CHS1).[97] Patients with Chédiak-Higashi syndrome present with partial oculocutaneous albinism, neutropenia, frequent infection, mild bleeding diathesis, and neurologic abnormalities. Approximately 85% of patients who survive childhood enter a so-called accelerated phase, a lymphoma-like infiltration of lymphocytes and histiocytes throughout the body that is generally fatal. Other diseases of neutrophil granules have less ominous prognoses. A novel immunodeficiency syndrome relating to lack of the endosomal adapter protein p14 (encoded by the *LAMTOR2* gene) has been described. Patients with this syndrome have congenital neutropenia with structurally abnormal neutrophil primary granules and abnormalities of B cells, cytotoxic T cells, and melanocytes. In addition to immunodeficiency, clinical findings include short stature and partial albinism.[98]

## Oxidase Deficiencies—Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) resembles other diseases of neutrophil dysfunction in that it results in severe, recurrent infections of the skin and mucous membranes. Osteomyelitis and intra-abdominal abscesses are common. As a result of the inability to kill organisms, accumulation of neutrophils at a site of infection generally results in granuloma formation, rather than clearance of the target. Cutaneous infections tend to show persistent drainage and

scarring. The presence of even partially responsive neutrophils results in a lower frequency of sepsis in these patients relative to patients with absolute neutropenia. CGD is typically a disease of early childhood, although some milder cases may be recognized later in life.

CGD encompasses a group of diseases. In each, a genetic defect in a different component of NADPH oxidase results in failure of neutrophils (and other phagocytes) to generate $O_2^-$, impairing both intra-cellular killing and the ability of neutrophils to generate NETs.[45,46] X-linked CGD affecting $gp91^{phox}$ (the *CYBB* gene) is the most common form and accounts for about 70% of cases, whereas the autosomal recessive forms are responsible for the remainder.[99,100]

Treatment for CGD consists of aggressive antibiotic prophylaxis and therapy, along with long-term therapy with recombinant human IFN-γ to improve neutrophil function. Clinical trials of gene therapy for X-linked CGD have thus far yielded equivocal results.[101]

### Defects of TLR Signaling

Defects in human TLR signaling including IRAK-4 and MyD88 deficiencies lead to impaired neutrophil function and increased susceptibility to bacterial infections.[102,103]

## NEUTROPHIL RELEVANCE TO RHEUMATIC DISEASE

### Neutrophil-Mediated Tissue Destruction

Despite sophisticated regulatory mechanisms, tissue destruction by neutrophils is common. Several mechanisms may permit the release of neutrophil proteases and oxygen radicals into the extra-cellular milieu. First, necrosis or destruction of neutrophils, or both, may liberate cellular contents indiscriminately. Second, studies have revealed that degranulation and $O_2^-$ generation may begin before complete closure of the phagocytic vacuole, releasing products either into the external environment (regurgitation during feeding) or against a target surface. Neutrophils may destroy host tissues that they have been misdirected to attack. Although serum and joint fluid contain anti-proteases and antioxidants, the "protected space" between a neutrophil and a surface (e.g., cartilage) may exclude these factors. Release of hypochlorous acid, MPO, and proteinases into the extra-cellular milieu may also inactivate protective compounds and act as an "anti-proteinase shield."[37]

### Neutrophil Fc Receptor Polymorphisms

Given that polymorphisms of FcγR determine phagocytic capacity of IgG isotypes, it is not surprising that they determine susceptibility to diseases in which autoantibodies play a key role. Phagocytes from persons with one FcγRIIa polymorphism (H131) allele are able to bind and phagocytose $IgG_2$, whereas phagocytes from persons with a different polymorphism (R131) cannot do so. In white European and African American populations, patients with lupus nephritis have a higher frequency of the FcγRIIa-R131 allele than do control groups; their relative inability to clear immune complexes may make them more susceptible to renal disease.[104] The significance of different Fc receptor polymorphisms may vary among rheumatologic diseases. Tse and colleagues[104a,104b] found no association between FcγRIIa polymorphisms and likelihood of developing anti-neutrophil cytoplasmic antibody (ANCA)–associated vasculitides, but they found an overrepresentation of homozygosity for the FcγRIIIb NA1 allele among patients with anti-myeloperoxidase antibodies. Few studies have been published on Fc polymorphisms and susceptibility or severity of RA. Authors of more recent studies found no association among FcγRIIa, IIb, or IIIb haplotypes and rheumatoid arthritis susceptibility but did find a correlation between patients with extra-articular disease and the homozygous R/R 131 genotype. In contrast, FcγRIIIa receptor expression is increased in persons with RA.[105]

### Gout

Gout is the quintessential neutrophilic rheumatic disease. Although the initiation of an acute gouty attack involves the phagocytosis of urate crystals by synovial macrophages and macrophage generation of cytokines such as IL-1 and IL-8, the hallmark of acute gout is the presence of enormous numbers of neutrophils (sometimes >100,000/$mm^3$) in the affected synovial fluid. Intra-articular urate crystals nonspecifically bind immunoglobulin and activate complement by the classic and alternative pathways. C5a liberated by this process attracts neutrophils to the joint space, where they phagocytose opsonized crystals via receptor-dependent mechanisms, resulting in further activation of the neutrophil and production of $LTB_4$, IL-8, and other mediators, promoting ingress of additional neutrophils. Naked urate crystals can also directly activate neutrophils. Neutrophils in the gouty joint may damage joint structures through discharge of contents directly into the joint fluid during crystal phagocytosis or directly against cartilage during attempted phagocytosis of urate crystals embedded in or adherent to cartilage. Interaction of phagocytosed urate crystals with lysosomal membranes additionally results in the dissolution of the latter, spilling lysosomal proteases into the cytoplasm and, eventually, into the extra-cellular space.[106] Perhaps surprisingly, recent studies implicate NETs as playing a role in the resolution, rather than the activation, of gouty inflammation. As increasing numbers of neutrophils are recruited to the synovial fluid, NETs aggregate and promote degradation of inflammatory mediators, and thereby contribute to breaking the inflammatory cycle.[107]

### Rheumatoid Arthritis

RA may be conceptualized as a two-compartment inflammatory disease. In the synovium, lymphocytes, fibroblasts, and macrophages predominate, but the joint space contains mainly neutrophils. The classic model suggests that rheumatoid factor and/or anti-citrullinated protein antibody (ACPA)–based immune complexes, produced in the pannus (inflamed synovium) and present in the joint space in high concentrations, can activate complement to recruit neutrophils into the joint space. The ability of rheumatoid fibroblast–like synoviocytes to secrete IL-1, IL-8, and other cytokines indicates that pannus itself can play an important role in attracting neutrophils out of the bloodstream and into the joint. Conversely, neutrophils in the RA joint may

contribute to the propagation of pannus. RA neutrophils produce pro-inflammatory cytokines that may act on synovium, including oncostatin M, MIP-1α, and IL-8.[108] In animal models, injection of lysates of neutrophil granules into joints produces a synovitis histologically indistinguishable from rheumatoid synovitis, an effect that can be reproduced by injection with purified active or inactive myeloperoxidase.[109]

Neutrophil proteinase 3 may enhance the pro-inflammatory impact of synovial macrophages by cleaving and releasing active IL-1 and TNF from the surface of the latter. Neutrophil defensins enhance phagocytosis by macrophages and stimulate the activation and degranulation of mast cells, an interesting observation in light of a report that mice deficient in mast cells are resistant to the development of erosive arthritis.[110] Neutrophil proteases also enhance the adherence of rheumatoid synovial fibroblasts to articular cartilage, and neutrophils may regulate synovial vascularization through the production of vascular endothelial growth factor, leading to endothelial proliferation. Studies by Lee and others confirm that neutrophils are necessary for the propagation of rheumatic disease in mouse models of RA. These studies implicate the ability of neutrophils to produce $LTB_4$, as well as the presence of FCγRIIA and C5a receptors on the neutrophil surface as necessary for arthritis development.[111,112] Several studies have raised the unexpected possibility that, under certain conditions of stimulation, neutrophils can serve as antigen-presenting cells. Neutrophils in rheumatoid arthritis synovial fluid synthesize and express large amounts of class II major histocompatibility complex.

## Systemic Lupus Erythematosus

Until recently, the role of the neutrophil in lupus was considered to be limited to its function as an inflammatory effector. However, the discovery of NETs led to renewed interest in the role of neutrophils in pathogenesis, not only through endothelial damage but also in the induction of autoimmunity. NETs express several autoantigens that are targets of lupus autoantibodies.[113] As previously mentioned, although peptidylarginine deiminase facilitates NET formation, its inhibition is protective against organ damage in a model of murine lupus.[114] NETs can be dismantled by DNase, and some patients with lupus cannot degrade NETs because of inhibitors of or antibodies to DNase. The inability to degrade NETs correlates with the presence of lupus nephritis.[115] Moreover, it was reported that patients with low NET-degrading activity in their sera have higher levels of autoantibodies and lower levels of C3 and C4 compared with patients who have high NET-degrading activity in their sera, because NETs that are not degraded bind and activate complement.[116] NETs may also contribute to the IFN-α signature in systemic lupus erythematosus (SLE) because they induce IFN-α production by plasmacytoid dendritic cells in a TLR9-dependent manner.[117]

## Vasculitis

Neutrophils may be identified, to a greater or lesser degree, in the lesions of virtually all kinds of vasculitis. The mechanisms of neutrophil accumulation may vary, however, with different mechanisms predominating in different conditions. The early observation that infusions of allospecies serum produced acute inflammation in skin and joints (serum sickness), together with the appreciation that subcutaneous re-challenge with previously administered antigen leads to intense local inflammation (the Arthus reaction), led to the development of a model in which immune complex deposition in blood vessels results in complement activation and an influx of neutrophils. Because immune complex formation is a hallmark of many small vessel vasculitides (e.g., essential mixed cryoglobulinemia, hypersensitivity vasculitis, and Henoch-Schönlein purpura), it is likely that immune complex deposition is crucial to the genesis of these diseases. In several of these conditions, neutrophil disruption and fragmentation—*clasis*—is a prominent pathologic finding, leading to their designation under the rubric *leukocytoclastic vasculitis*. In some rheumatic diseases in which vasculitis is a secondary phenomenon, such as RA and SLE, the role of immune complex deposition is implicit. It has been suggested that patients with lupus experience transient accumulations of neutrophils (leukoaggregation) in small vessels of the lungs and other tissues as a result of complement activation within these vessels or in the soluble phase.[118]

Induction of adhesion molecules on endothelial cells, neutrophils themselves, or both is an alternative mechanism through which neutrophil accumulation in vessels may be propagated. The Shwartzman phenomenon, in which reinjection of cellular material leads to vascular inflammation via a cytokine-dependent, immune complex–independent mechanism, is a model for this avenue to vasculitis. Adhesion molecule upregulation may be particularly relevant to vasculitides in which immune complex formation is not a hallmark. It is likely that many rheumatic diseases employ both immune complex–dependent and immune complex–independent mechanisms in the pathogenesis of neutrophil ingress into vascular structures. For example, in addition to the role of immune complexes, Belmont and colleagues have shown the induction of adhesion molecules in patients with SLE.[119]

Several vasculitides are noteworthy for the presence, in the serum of affected patients, of antibodies directed at cytoplasmic components of neutrophils (ANCA). In these diseases, partial neutrophil degranulation, resulting in exposure of ANCA antigens (e.g., MPO and proteinase 3), appears to be critical for disease pathogenesis. $ANCA^+$ vasculitides are discussed in detail in Chapter 89.

## Neutrophilic Dermatoses and Familial Mediterranean Fever

Sweet's syndrome is characterized by fever, neutrophilia, and painful erythematous papules, nodules, and plaques. The syndrome may be idiopathic, parainflammatory (i.e., associated with inflammatory bowel disease or infection), paraneoplastic (most commonly in the setting of leukemia), pregnancy related, or drug associated (usually after treatment with G-CSF). Clinically, Sweet's syndrome is a diagnosis of exclusion. Sweet's syndrome frequently appears after an upper respiratory tract infection and has a propensity to involve the face, neck, and upper extremities. When found on the legs, Sweet's syndrome lesions can be confused

with erythema nodosum. Histopathologic features are characterized by dense neutrophilic infiltrate in the superficial dermis and edema of the dermal papillae and papillary dermis. Leukocytoclasia may suggest leukocytoclastic vasculitis, although vascular damage is absent. It is typically accompanied by peripheral neutrophilia. Treatment with systemic corticosteroids usually induces a dramatic resolution of the lesions and the systemic symptoms. Although the cause of the disease is unclear, many investigators believe that Sweet's syndrome may represent a hypersensitivity reaction to microbial or tumor antigens. Antibiotics do not influence the course of the disease in most patients.

Pyoderma gangrenosum is characterized by painful ulcerating cutaneous lesions over the lower extremities, usually in patients with an underlying inflammatory illness. Inflammatory bowel disease, RA, and seronegative arthritis are the most common associations, although an association with malignancy has also been reported. Fifteen percent of patients have a benign monoclonal gammopathy, usually IgA. Like Sweet's syndrome, pyoderma gangrenosum is a diagnosis of exclusion, is characterized on biopsy specimen by neutrophilic infiltrate, and usually remits with systemic corticosteroids, although topical and intralesional injections of corticosteroids may be beneficial as well. Other rare neutrophilic dermatoses include rheumatoid neutrophilic dermatitis, described as symmetric erythematous nodules on extensor surfaces of joints; bowel-associated dermatosis-arthritis syndrome occurring after bowel bypass surgery for obesity; and neutrophilic eccrine hidradenitis, which is sometimes linked to acute myelogenous leukemia.

In familial Mediterranean fever (discussed in detail in Chapter 97), patients experience episodic inflammatory exacerbations characterized by large influxes of neutrophils. A defect in the regulatory protein pyrin seems to permit the inappropriate development of inflammation, leading to its categorization as an autoinflammatory disease. Pyrin is expressed primarily in myeloid cells, including neutrophils and eosinophils.

## Effects of Anti-rheumatic Agents on Neutrophil Functions

Many anti-rheumatic therapies currently in use have been documented to act at least partly at the level of the neutrophil. Nonsteroidal anti-inflammatory drugs (NSAIDs) are the most frequently used class of anti-rheumatic agents. By virtue of their ability to inhibit COX activity and prostaglandin production, moderate doses of NSAIDs have diverse effects on inflammation, including inhibition of vascular permeability and modulation of pain. At higher, clinically anti-inflammatory concentrations, NSAIDs inhibit chemoattractant-stimulated neutrophil CD11b/CD18-dependent adhesion and degranulation and NADPH oxidase activity.[120,121] It is unlikely, however, that these effects are due solely to COX inhibition because (1) as noted earlier, neutrophils exhibit little COX activity under normal circumstances, and (2) concentrations of NSAIDs required to inhibit neutrophil function exceed the concentrations required to inhibit COX. Salicylates may be unique as NSAIDs because of their ability to promote lipoxin formation to inhibit neutrophil cell signaling at high concentrations.[122]

### Glucocorticoids

Glucocorticoids exert potent effects on neutrophils, including inhibition of neutrophil phagocytic activity and adhesive function. The ability of steroids to increase peripheral blood neutrophil populations acutely—an effect known as *demargination*—is attributable to both a release of neutrophils from the bone marrow and the release (demargination) of neutrophils adherent to vessel walls. In addition, glucocorticoids lead to inhibition of phospholipase $A_2$ and LT and prostaglandin production. Glucocorticoids may also regulate the expression of COX-2 and stimulate the release of annexin A1, which inhibits arachidonate release from membranes. Effects of glucocorticoids on other cells may also reduce neutrophil responses indirectly through the suppression of cytokines at inflammatory sites.

### Disease-Modifying Anti-rheumatic Drugs

Several disease-modifying anti-rheumatic drugs have well-established effects on neutrophils. Methotrexate, which is widely used in persons with RA, has no direct neutrophil effect but is capable of producing indirect effects, probably by virtue of its ability to stimulate the release of adenosine from surrounding cells. Some data suggest that methotrexate-induced adenosine release might inhibit phagocytosis, $O_2^-$ production, and adhesion, and treatment of patients with methotrexate inhibits the capacity of neutrophils to generate $LTB_4$.[123] Sulfasalazine has been shown to inhibit neutrophil chemotaxis, degranulation, and $O_2^-$ generation; decrease $LTB_4$ production; and scavenge oxygen metabolites.[120]

### Colchicine

Colchicine, a standard agent in the treatment of gout and familial Mediterranean fever, inhibits microtubule formation and has pleiotropic effects on neutrophils, including inhibition of adhesion via decrements in selectin expression.[124] Colchicine has been observed to stimulate the expression of pyrin in neutrophils. Because pyrin deficiencies are implicated in familial Mediterranean fever, this observation suggests a previously unappreciated mechanism of action of colchicine in neutrophilic diseases.[125]

### Biologic Agents

The current era of biologic therapies has been ushered in through the introduction of agents designed to block the effects of TNF or IL-1β. As noted earlier, IL-1β and TNF directly affect neutrophil function, including priming for stimulus-induced responses such as $O_2^-$ production, cartilage destruction, and production of cytokines such as IL-8 and $LTB_4$. Nonetheless, studies examining the effects of anti-TNF treatment on neutrophil function measured ex vivo have not indicated extensive action. Treatment of patients with etanercept or adalimumab induced no effect on neutrophil ex vivo responses including chemotaxis, phagocytosis, and superoxide generation (although CD69 levels were reduced).[126,127] Reduction of neutrophil populations in RA joint effusions after anti-TNF therapy is more likely due to alteration of the inflammatory environment

rather than to direct effects on the neutrophils themselves. Similarly, recent studies indicate that anti-IL-6 therapy with tocilizumab may induce neutropenia in patients but has no direct effect on neutrophil function.[128]

## CONCLUSION

The complex machinery of neutrophil surveillance and response—the chemotactic, phagocytic, enzymatic and oxidative defenses that enable neutrophils to sense and destroy foreign organisms—provide robust host defense by aborting many forms of infection and keeping others at bay until more specific mechanisms can be mobilized. When improperly regulated, however, these same mechanisms become the basis of inflammatory and autoinflammatory disease and potentially lead to tissue destruction. Moreover, it is increasingly appreciated that neutrophils play critical roles in bridging the gap between innate and acquired immunity. In several rheumatic diseases, the neutrophil therefore serves not merely as an effector cell but as a direct participant in disease pathogenesis.

CHAPTER 12

# T Lymphocytes

Ralph C. Budd • Karen A. Fortner

**KEY POINTS**

- **T cells develop primarily in the thymus. The importance of the thymus is underscored by the complete absence of T cells in patients in whom a thymus has failed to develop (e.g., complete DiGeorge syndrome).**
- **Thymic selection consists of a positive phase in which T cells must recognize self–major histocompatibility complex (MHC) molecules and a negative phase in which thymocytes bearing high-affinity T cell receptors for self-MHC peptide are deleted through apoptosis.**
- **T cells emerge from the thymus as naïve T cells that are quiescent and, when activated, express low to negligible levels of most cytokines. Once they acquire a memory phenotype ($CD45RO^+$), they can produce high levels of cytokines.**
- **Naïve T cells can spontaneously undergo homeostatic proliferation to self-MHC peptides in peripheral lymphoid tissues to generate a critical number of T cells. This process requires IL-7 and IL-15.**
- **Th1 and Th17 cells accumulate in inflammatory synovium such as rheumatoid arthritis, whereas Th2 cells accumulate at sites of allergic responses such as asthma.**

The evolutionary pressures that have molded the immune response and promoted a highly diverse repertoire clearly derive from infectious agents. Two very different strategies exist. The more primitive innate immune response (see Chapter 17) uses a limited repertoire of nonpolymorphic receptors that recognize structural motifs common to many micro-organisms, such as small glycolipids and lipopeptides. The evolutionarily newer adaptive immune response (see Chapter 18) relies on generating myriad different receptors that can recognize a wide array of foreign compounds from infectious agents. Whereas the innate immune response allows a rapid focused response, adaptive immunity permits a broader, albeit slower, response, as well as immune memory.

T lymphocyte development constantly confronts the dilemma of generating pathogen-specific T cells to combat infection without provoking a response to the host. The price for generating an increasingly varied population of antigen receptors needed to recognize a wide spectrum of pathogens is the progressive risk of producing self-reactive lymphocytes that can provoke an autoimmune diathesis. T lymphocytes are thus subjected to a rigorous selection process during development in the thymus to delete self-reactive T cells (i.e., central tolerance). In addition, premature activation of mature peripheral T cells is prevented by requiring two signals for activation (i.e., peripheral tolerance). Finally, the expansion of T cells that occurs during either homeostatic proliferation in the periphery or in response to an infection is resolved by the active induction of cell death. The consequences of inefficient lymphocyte removal at any one of these junctures can be devastating to the health of the organism. This situation is vividly displayed in both humans and mice when naturally arising mutations in death receptors such as Fas (CD95) result in massive accumulation of lymphocytes and autoimmune sequelae. These sequelae are discussed in more detail in Chapter 28.

The activation of T lymphocytes yields a variety of effector functions that are pivotal to combating infections. Cytolytic T cells can kill infected cells through the release of granules containing perforin and granzyme that induce holes in cell membranes and cleave cellular substrates, respectively, or through the expression of ligands for death receptors such as Fas or tumor necrosis factor (TNF) receptor. Production of T cell cytokines such as interferon-γ (IFN-γ) can inhibit viral replication, whereas other cytokines such as interleukin (IL)-4, IL-5, and IL-21 are critical for optimal B cell growth and immunoglobulin production.[1] However, this same armamentarium, if not tightly regulated, can also precipitate damage to host tissues and provoke autoimmune responses, such as in the synovium of inflammatory arthritides, pancreatic islets in type 1 diabetes, and the central nervous system in multiple sclerosis. Damage in these cases need not be directly the result of recognition of target tissues by the T cells. T cells may be activated elsewhere and then migrate to the tissue and damage innocent bystander cells. T cells may also promote autoimmunity through the augmentation of B cell responses.

## T CELL DEVELOPMENT

T cells must traverse two stringent hurdles during their development. First, they must successfully rearrange the genes encoding the two chains of the T cell antigen receptor (TCR). Second, a T cell must survive thymic selection during which T cells that interact strongly with self-peptides are eliminated (i.e., negative selection). This process minimizes the chances of autoreactive T cells escaping to the periphery and is known as *central tolerance*.

The TCR is an 80 to 90 kDa disulfide-linked heterodimer composed of a 48 to 54 kDa α chain and a 37 to 42 kDa β chain. An alternate TCR composed of γ and δ

chains is expressed on 2% to 3% of peripheral blood T cells (discussed later). The TCR has an extra-cellular ligand binding pocket and a short cytoplasmic tail that by itself cannot signal. Consequently it is noncovalently associated with as many as five invariant chains of the CD3 complex, which relay information to the intra-cellular signaling machinery via immunoreceptor tyrosine-based activation motifs (ITAMs; discussed later). Not surprisingly, the structure of the TCR gene is similar to that of immunoglobulin genes in B cells (see details in Chapter 13). Each overcame the problem of how to encode approximately 10 million different T or B cell specificities within the human genome, which contains fewer than 30,000 genes. To economically package this diversity, the process of gene rearrangement and splicing evolved using machinery similar to what already existed to promote gene translocations. The β and δ chain genes of the TCR contain four segments known as the V (variable), D (diversity), J (joining), and C (constant) regions. The α and γ chains are similar but lack the J component. Each of the segments has several family members (approximately 50 to 100 V, 15 D, 6 to 60 J, and 1 to 2 C members). An orderly process occurs during TCR gene rearrangement in which a D segment is spliced adjacent to a J segment, which is subsequently spliced to a V segment. After transcription, the VDJ sequence is spliced to a C segment to produce a mature TCR messenger RNA (mRNA). Arithmetically, this random rearrangement of a single chain of the TCR locus can give rise to minimally 50V × 15D × 6J × 2C or about 9000 possible combinations. At each of the splice sites, which must occur in-frame to be functional, additional nucleotides not encoded by the genome (so-called N-region nucleotides) can be incorporated, adding further diversity to the rearranging gene. The combinations from the two TCR chains, plus N-region diversity, yield at least $10^8$ theoretical possible combinations. The cutting, rearranging, and splicing are directed by specific enzymes. Mutations in the genes for these processes can result in an arrest in lymphocyte development. For example, mutation in the gene encoding a DNA-dependent protein kinase required for receptor gene recombination results in a severe combined immunodeficiency known as *scid*.

Because the developing T cell has two copies of each chromosome, there are two chances to successfully rearrange each of the two TCR chains. As soon as successful rearrangement occurs, further β chain rearrangements on either the same or the other chromosome are suppressed, a process known as *allelic exclusion*, which limits the chance of dual TCR expression by an individual T cell. The high percentage of T cells that contain rearrangements of both β chain genes attests to the inefficiency of this complex event. Rearrangement of the α chain occurs later in thymocyte development in a similar fashion, although without apparent allelic exclusion, which can result in dual TCR expression by a single T cell.

Development of T cells occurs within a microenvironment provided by the thymic epithelial stroma. The thymic anlage is formed from embryonic ectoderm and endoderm and is then colonized by hematopoietic cells, which give rise to dendritic cells, macrophages, and developing T cells. The hematopoietic and epithelial components combine to form two histologically defined compartments—the cortex, which contains immature thymocytes, and the medulla, which contains mature thymocytes (Figure 12-1A). As few as 50 to 100 bone marrow–derived stem cells enter the thymus daily.

The stages of thymocyte development can be defined by the status of rearrangement and expression of the two genes that encode the α and β chains of the TCR and the expression of CD4 and CD8, proceeding in an orderly fashion from $CD4^-8^- \rightarrow CD4^+8^+ \rightarrow CD4^+8^-$ or $CD4^-8^+$ (Figure 12-1B). CD4 and CD8 define the helper and cytolytic subsets of mature T cells, respectively.

$CD4^-8^-$ thymocytes can be further subdivided based on their expression of CD25 (the high-affinity IL-2 receptor α chain) and CD44 (the hyaluronate receptor). Development proceeds in the following order: $CD25^-CD44^+ \rightarrow CD25^+CD44^+ \rightarrow CD25^+CD44^- \rightarrow CD25^-CD44^-$. These subpopulations correspond to discrete stages of thymocyte differentiation. $CD25^-44^+$ cells express low levels of CD4, and their TCR genes are in germline configuration. These cells downregulate CD4 and upregulate CD25 to give rise to $CD25^+CD44^+$ thymocytes, which now express surface CD2 and low levels of CD3ε. At the next stage ($CD25^+CD44^-$), a brief burst of proliferation occurs, followed by upregulation of the recombination-activating enzymes, RAG-1 and RAG-2, and the concomitant rearrangement of the genes of the TCR β chain. A small subpopulation of T cells rearranges and expresses a second pair of TCR genes known as γ and δ. Productive TCR β chain rearrangement results in downregulation of RAG and a second proliferative burst. Loss of CD25 then yields $CD25^-CD44^-$ thymocytes.

The TCR β chain cannot be stably expressed without an α chain. Because the TCR α chain has not yet rearranged, a surrogate invariant TCR pre–α chain is disulfide linked to the β chain. When associated with components of the CD3 complex, this allows a low level surface expression of a pre-TCR and progression to the next developmental stage. Failure to successfully rearrange the TCR β chain results in a developmental arrest at the transition from $CD25^+CD44^-$ to $CD25^-CD44^-$. This developmental arrest occurs in RAG-deficient mice, as well as in *Scid* mice and humans.[2]

A number of transcription factors, receptors, and signaling molecules are required for early T cell development (Figure 12-2). IKAROS encodes a transcription factor required for the development of cells of lymphoid origin. Notch-1, a molecule known to regulate cell fate decisions, is also required at the earliest stage of T cell lineage development.[3] Cytokines, including IL-7, promote the survival and expansion of the earliest thymocytes. In mice that are deficient for IL-7, its receptor components IL-7Rα or $\gamma_c$, or the cytokine receptor–associated signaling molecule JAK-3, thymocyte development is inhibited at the $CD25^-CD44^+$ stage. In humans, mutations in $\gamma_c$ or JAK-3 result in the most frequent form of SCID.[4] Pre-TCR signaling is required for the $CD25^+CD44^- \rightarrow CD25^-CD44^-$ transition. Thus loss of signaling components including Lck, SLP-76, and LAT-1 results in a block at this stage of T cell development. TCR signals are also required for differentiation of $CD4^+CD8^+$ to mature $CD4^+$ or $CD8^+$ cells. Humans deficient in ZAP-70 (see later discussion) have $CD4^+$ but not $CD8^+$ T cells in the thymus and periphery.[5]

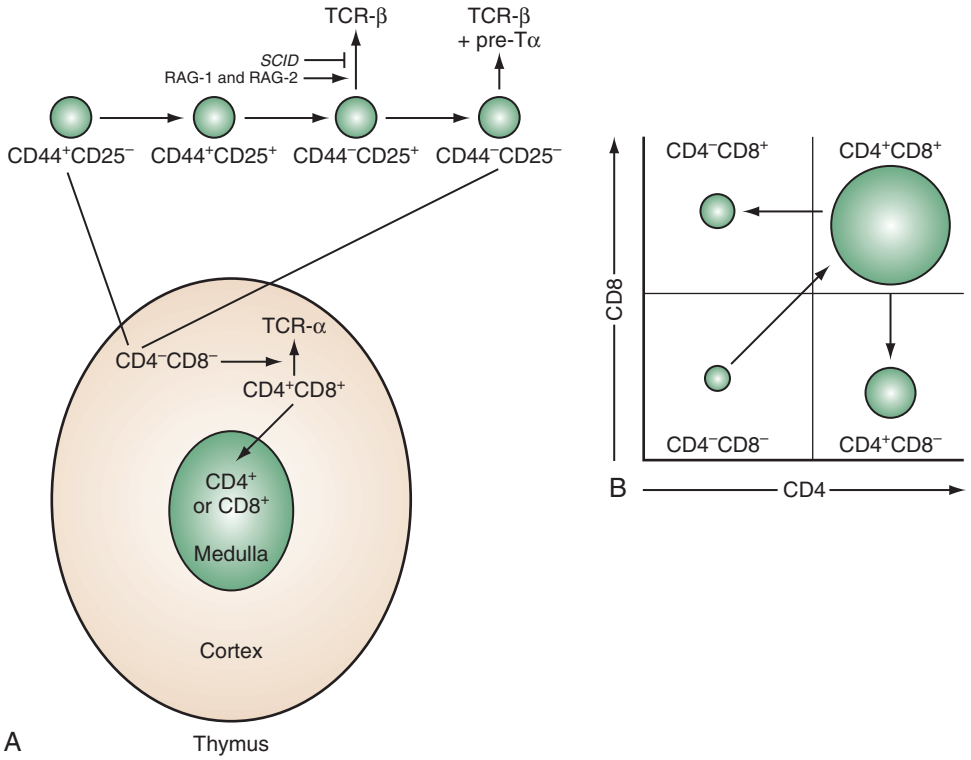

**Figure 12-1** Sequence of thymocyte development. **A,** The earliest thymocyte precursors lack expression of CD4 and CD8 ($CD4^-CD8^-$). These can be further divided into four subpopulations based on the sequential expression of CD44 and CD25. It is at the $CD44^-CD25^+$ stage that the T cell antigen receptor (TCR) β chain rearranges. The *SCID* mutation or deficiencies of the rearrangement enzymes RAG-1 and RAG-2 result in inability to rearrange the β chain and maturational arrest at this stage. The thymocytes that successfully rearrange the β chain express it associated with a surrogate α chain known as pre-Tα. Concomitant with a proliferative burst, development can then progress to the $CD4^+CD8^+$ stage in the cortex where the TCR α chain rearranges and pairs with the β chain to express a mature TCR complex. These cells then undergo thymic positive and negative selection (as diagrammed in Figure 3B). Successful completion of this rigorous selection process results in mature $CD4^+$ or $CD8^+$ T cells in the medulla, which eventually emigrate to peripheral lymphoid sites. **B,** Schematic two-color flow cytometry showing subpopulations of thymocytes defined by CD4 and CD8 expression in their relative proportions.

$CD25^-CD44^-$ cells upregulate expression of CD4 and CD8 to become $CD4^+8^+$, at which point the α chain of the TCR rearranges. Unlike the β chain, allelic exclusion of the α chain is not apparent. Rearrangement of the α chain can occur simultaneously on both chromosomes, and if one attempt is unsuccessful, repeat rearrangements to other Vα segments are possible. Reports exist of dual TCR expression by as many as 30% of mature T cells in which the same T cell expresses different α chains paired with the same β chain.[6] However, in most cases of dual TCR α chains, one is downregulated during positive selection by Lck and Cbl, through ubiquitination, endocytosis, and degradation.

Although the structure of immunoglobulin and TCR are quite similar, they recognize fundamentally different antigens. Immunoglobulins recognize intact antigens in isolation, either soluble or membrane bound, and are often sensitive to the tertiary structure. The TCRαβ recognizes linear stretches of antigen peptide fragments bound within the grooves of either class I or class II major histocompatibility complex (MHC) molecules (Figure 12-3A). Thymic selection molds the repertoire of emerging TCRs so they recognize peptides within the groove of self-MHC molecules, ensuring the *self-MHC restriction* of T cell responses. The MHC structure is described in detail in Chapters 18, 19, and 21. Pockets within the MHC groove bind particular residues along the peptide sequence of 7-9 amino acids for class I MHC and 9-15 amino acids for class II MHC molecules. As a result, certain amino acids will make strong contact with the MHC groove, whereas others will contact the TCR.

The contact between the TCR and MHC/peptide has been revealed by crystal structure to be remarkably flat, rather than a deep lock and key structure that one might imagine.[7] The TCR axis is tipped about 30 degrees to the long axis of the class I MHC molecule and is slightly more skewed to class II MHC. The affinity of the TCR for antigen/MHC is in the micromolar range, which is a lower affinity than many antibody-antigen affinities, and several logs less than many enzyme-substrate affinities. This finding has led to the notion that TCR interactions with antigen/MHC are brief and that successful activation of the T cell requires multiple interactions, resulting in a cumulative signal.

Once the T cell has successfully rearranged and expressed a TCR in association with the CD3 complex, it encounters the second major hurdle in T cell development, *thymic selection*. Selection has two phases, positive and negative, and the outcome is based largely upon the intensity of TCR signaling in response to interactions with MHC/self-peptides expressed on thymic epithelium and dendritic cells. TCR signals that are either too weak (death by neglect) or too intense *(negative selection)* result in elimination by apoptosis, whereas those with intermediate signaling intensity

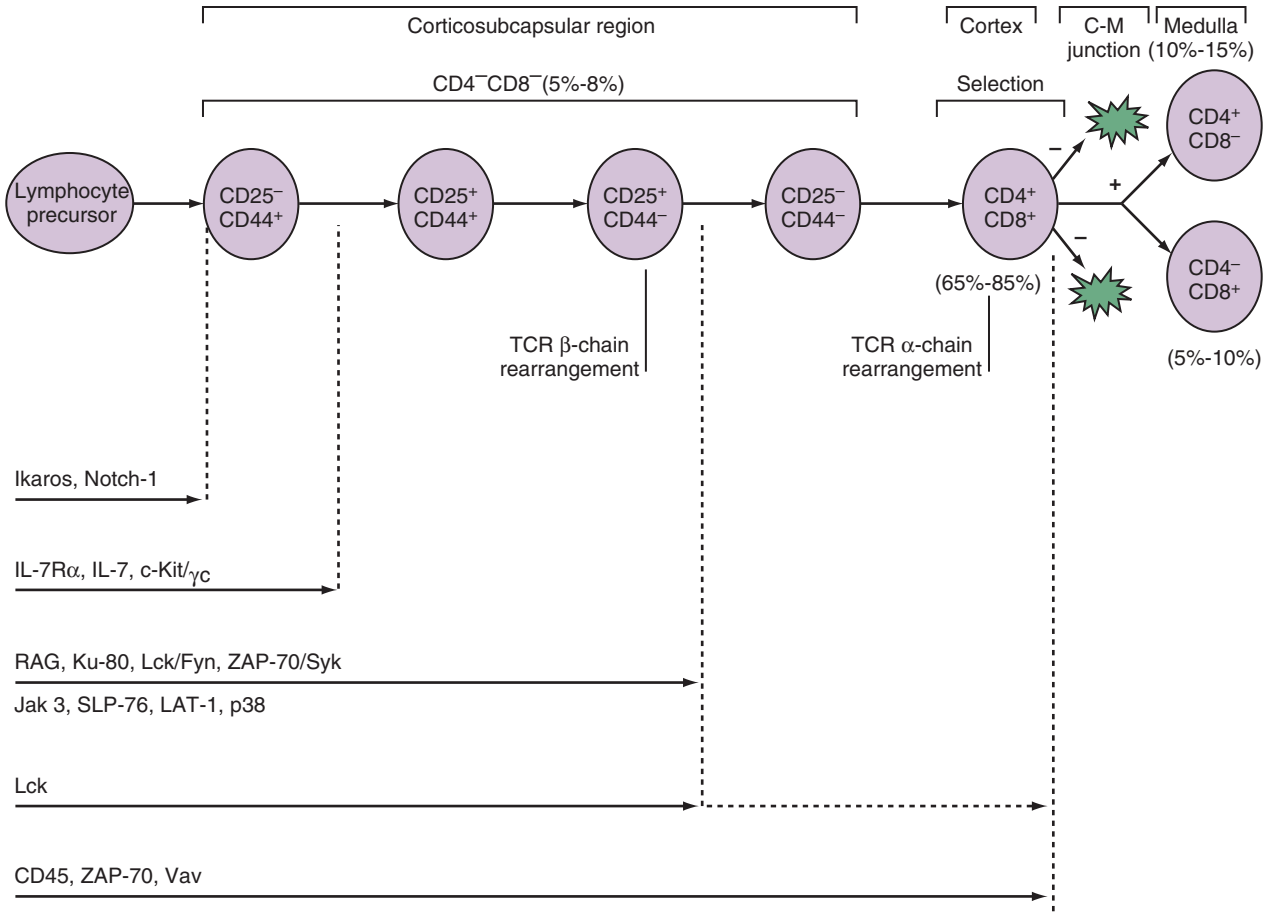

**Figure 12-2** Sequence of αβ T cell development in the thymus. The earliest thymocyte precursors lack expression of CD4 and CD8 ($CD4^-CD8^-$). These can be further divided into four subpopulations based on the sequential expression of CD25 and CD44. At the $CD25^+CD44^-$ stage, the T cell antigen receptor (TCR) β chain rearranges and associates with a surrogate α chain known as pre-Tα. Concomitant with a proliferative burst, thymocytes progress to the $CD4^+CD8^+$ stage, rearrange the TCR α chain, and express a mature TCR complex. These cells then undergo thymic positive and negative selection (as diagrammed in Figure 12-3B). The thymocytes that survive this rigorous selection process differentiate into mature $CD4^+$ or $CD8^+$ T cells. Also shown are the various signaling molecules that are involved at specific stages of thymic development.

survive *(positive selection)* (Figure 12-3B). Successful positive selection at the $CD4^+8^+$ stage is coincident with upregulation of surface TCR, the activation markers CD5 and CD69, and the survival factor Bcl-2. T cells bearing a TCR that recognizes class I MHC maintain CD8 expression, downregulate CD4, and become $CD4^-8^+$. T cells expressing a TCR that recognizes class I MHC become $CD4^+8^-$.

An enigma for thymic selection has been how to present the myriad self-proteins to developing thymocytes so that self-reactive thymocytes are effectively eliminated by negative selection, particularly including antigens with tissue or developmentally restricted expression. A solution was found with the discovery of the autoimmune regulator *(AIRE)* gene. AIRE is a transcription factor expressed by the medullary epithelium of the thymus that induces transcription of a wide array of organ-specific genes, such as insulin, that might otherwise be sequestered from developing thymocytes.[8] This effectively creates a self-transcriptome within the thymus against which autoreactive T cells can be deleted. Gene knockout mice of *Aire*, and humans bearing *AIRE* mutations, manifest various autoimmune sequelae in a syndrome known as autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED).[9]

Not surprisingly, a variety of signaling molecules activated by TCR engagement are important to thymic selection. Lck, the RasΠRaf-1ΠMEK1ΠERK kinase cascade, the kinase ZAP-70, and the phosphatases CD45 and calcineurin are involved with positive selection. Among these, the Ras ΠERK pathway is particularly important because dominant negative variants of these molecules can disrupt positive selection. Conversely, an activator of Ras known as GRP1 assists with the positive selection of thymocytes that express weakly selecting signals. These molecules are discussed in more detail in the section on TCR signaling. By contrast, although a number of molecules may promote negative selection—among them the mitogen-activated protein (MAP) kinases JNK and p38—there appears to be sufficient redundancy so that only rarely does elimination of any one of these molecules alter the efficient deletion of thymocytes. The few exceptions include CD40, CD40L, CD30, or the proapoptotic Bcl-2 family member, Bim, where preservation of at least some thymocytes bearing self-reactive TCR could be observed in mice deficient in these molecules.[10]

The survivors of these stringent processes of TCR gene rearrangement and thymic selection represent less than 3%

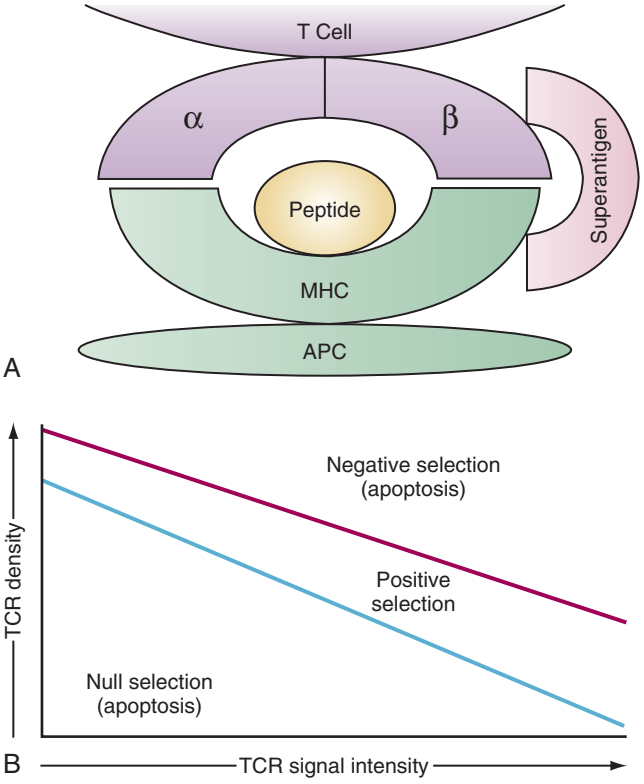

**Figure 12-3** T cell antigen receptor (TCR) interaction with the major histocompatibility complex (MHC)/peptide complex. **A,** Polymorphic residues within the variable region of the α and β chains of the TCR make contact with determinants on the MHC molecule on an antigen presenting cell (APC), as well as with the peptide fragment that sits in the MHC binding groove. **B,** A schematic diagram illustrating that during thymocyte development, the TCRs that confer either a very low signal intensity (null selection) or high intensity (negative selection) each lead to apoptosis. Only the thymocytes whose TCRs can engage MHC/peptides and confer moderate intensity survive by positive selection.

of total immature thymocytes, which is reflected by the presence of a high rate of cell death in developing thymocytes. This process can be visualized by the measurement of DNA degradation, a hallmark of apoptosis, as shown in Figure 12-4. The survivors become either $CD4^+$ helper or $CD8^+$ cytolytic T lymphocyte cells (CTLs) and reside in the thymic medulla for 12 to 14 days before emigrating to the periphery. The decision to become a $CD4^+$ versus $CD8^+$ T cell involves further developmental signals, provided in part by Notch-1, which is required for progression to $CD8^+$ but not $CD4^+$ thymocytes. This scenario parallels the observation that long TCR interactions are required for CD4 progression, whereas shorter TCR engagement favors CD8 progression.[11]

## Abnormalities of Human T Cell Development

Given the vast number of events in T cell development, it is not surprising that a multiplicity of causes can underlie human T cell immunodeficiencies.[12] The influence of the thymic stroma on thymocyte ontogeny is underscored in the DiGeorge anomaly in which development of the pharyngeal pouches is disrupted and the thymic rudiment fails to form, resulting in the failure of normal T cell development. Less severe T cell deficiencies are associated with a failure to express class I and/or class II MHC (the "bare lymphocyte syndrome"), which are directly involved with interactions required to induce the positive selection of, respectively, $CD8^+$ and $CD4^+$ mature T cells.

Metabolic disorders can affect thymocytes more directly. The absence of functional adenosine deaminase (ADA) and purine nucleoside phosphorylase (PNP) results in the buildup of metabolic byproducts that are toxic to developing T and B lymphocytes, ultimately producing forms of severe combined immunodeficiency disorders (SCIDs).

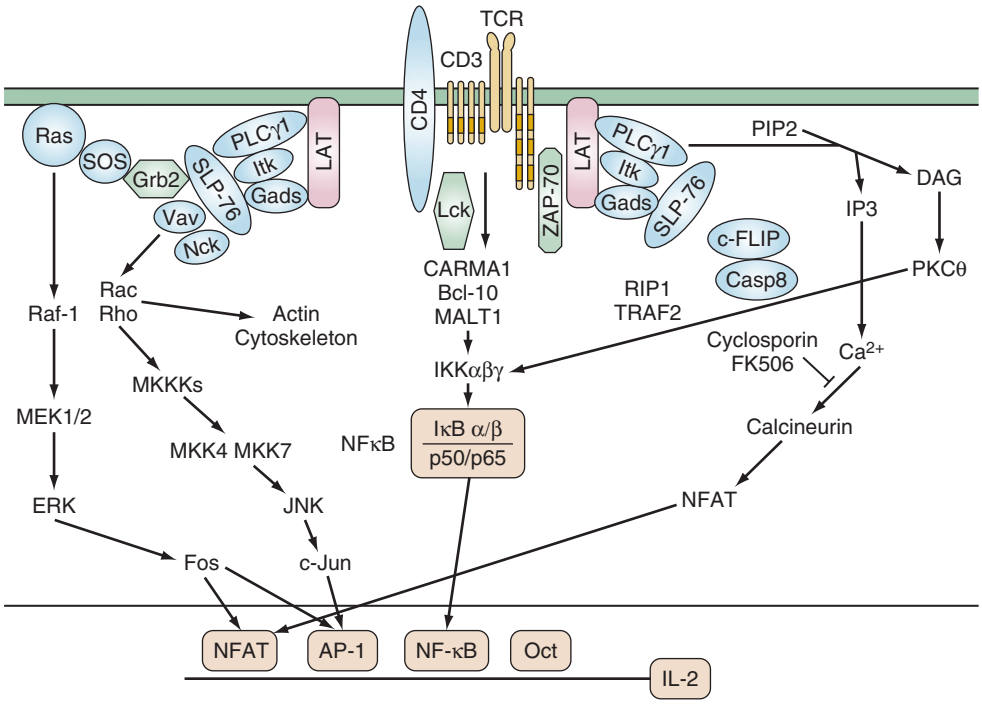

**Figure 12-4** T cell antigen receptor (TCR) signal pathways. The schema shows the principle signal pathways resulting from TCR activation and how they impinge on the regulatory region of the *IL2* gene. See the text for details.

## PERIPHERAL MIGRATION AND HOMEOSTATIC PROLIFERATION OF T CELLS

The migration of naïve T cells to peripheral lymphoid structures or their infiltration into other tissues requires the coordinated regulation of an array of cell adhesion molecules. T cell recirculation is essential for host surveillance and is carefully regulated by a specific array of homing receptors. Entry from the circulation to tissues occurs via two main anatomic sites: the flat endothelium of the blood vessels and specialized postcapillary venules known as high endothelial venules (HEVs). A three-step model has been described for lymphocyte migration: rolling, adhesion, and migration.[13] L-selectin expressed by naïve T cells binds via lectin domains to carbohydrate moieties of GlyCAM-1 and CD34 (collectively known as peripheral node addressin), which are expressed on endothelial cells, particularly HEV. The weak binding of CD62L to its ligand mediates a weak adhesion to the vessel wall, which, combined with the force of blood flow, results in rolling of the T cell along the endothelium. The increased cell contact facilitates the interaction of a second adhesion molecule on lymphocytes, the integrin LFA-1 (CD11a/CD18), along with its ligands, ICAM-1 (CD54) and ICAM-2 (CD102). This interaction results in the arrest of rolling and firm attachment. Migration into the extra-cellular matrix of tissues may involve additional lymphocyte cell surface molecules such as the hyaluronate receptor (CD44) or the integrin α4β7 (CD49d/β7), which binds the mucosal addressin cell adhesion molecule-1 (MAdCAM-1) on endothelium of Peyer's patches and other endothelial cells.

Other cytokines known as chemokines may contribute to lymphocyte homing. Chemokines are structurally and functionally related to proteins that bear an affinity for heparan sulfate proteoglycan and promote migration of various cell types.[14] The chemokines RANTES, MIP-1α, MIP-1β, MCP-1, and IL-8 are produced by a number of cell types including endothelium, activated T cells, and monocytes and are present at inflammatory sites such as rheumatoid synovium (see Chapter 69).

Once mature T cells have reached the peripheral lymphoid tissues of lymph node and spleen, they undergo a low level of turnover known as *homeostatic proliferation* in response to self-peptide/MHC complexes, IL-7, and IL-15.[15] This low level of turnover serves to maintain the number of peripheral T cells and can become accelerated in states of lymphopenia, such as after chemotherapy or irradiation.[16] Because homeostatic proliferation is driven by self-MHC/peptides and is thus inherently autoimmune, its acceleration could precipitate an autoimmune syndrome. In this regard, it is of interest that one of the standard murine models of autoimmunity is day 3 thymectomy, which results in lymphopenia and autoimmunity of various organs.[17] In addition, NOD diabetic mice have chronic lymphopenia that contributes to their diabetes,[18] and evidence of augmented homeostatic proliferation has been suggested to occur in rheumatoid arthritis (RA).[19]

### Activation of T Cells

T cell activation initiates an intra-cellular signaling cascade that ultimately results in proliferation, effector function, or death, depending on the intensity of the TCR signal and associated signals. To guard against premature or excessive activation, T cells have a requirement of two independent signals for full activation. Signal 1 is an antigen-specific signal provided by the binding of the TCR to antigenic peptide complexed with MHC. Signal 2 is mediated by either cytokines or the engagement of co-stimulatory molecules such as B7.1 (CD80) and B7.2 (CD86) on the antigen-presenting cell (APC). Receiving only signal 1 without co-stimulation results in T cell unresponsiveness or anergy, a process known as *peripheral tolerance*.

### TCR and Tyrosine Kinases

TCR αβ and γδ have very short cytoplasmic domains and by themselves are unable to transduce signals. The molecules of the noncovalently associated CD3 complex couple the TCR to intra-cellular signaling machinery (see Figure 12-4). The CD3 complex contains nonpolymorphic members known as CD3ε, CD3γ, CD3δ, as well as ζ and η chains that are alternatively spliced forms of the same gene and are not genetically linked to the CD3 complex. Although the functional stoichiometry of the TCR complex is not completely defined, current data indicate that each TCR heterodimer is associated with three dimers: CD3εγ, CD3εδ, and ζζ or ζ. CD3ε, -γ, and -δ have an immunoglobulin-like extra-cellular domain, a transmembrane region, and a modest cytoplasmic domain, whereas ζ contains a longer cytoplasmic tail. The transmembrane domains of ζ and the CD3 chains contain a negatively charged residue that interacts with positively charged amino acids in the transmembrane domain of the TCR.

None of the proteins in the TCR complex has intrinsic enzymatic activity. Instead, the cytoplasmic domains of the invariant CD3 chains contain conserved activation domains that are required for coupling the TCR to intra-cellular signaling molecules. These ITAMs contain a minimal functional consensus sequence of paired tyrosines (Y) and leucines (L): (D/E)XXYXXL$(X)_{6\text{-}8}$YXXL. ITAMs are substrates for cytoplasmic protein tyrosine kinases (PTKs), and upon phosphorylation they recruit additional molecules to the TCR complex.[20] Each ζ chain contains three ITAMs, whereas there is one in each of the CD3ε, -γ, and -δ chains. Thus each TCR complex can contain as many as 10 ITAMs.

Activation of PTKs is one of the earliest signaling events after TCR stimulation. Four families of PTKs are known to be involved in TCR signaling: Src, Csk, Tec, and Syk. The Src family members Lck and $Fyn^T$ have a central role in TCR signaling and are expressed exclusively in lymphoid cells. Src PTKs contain multiple structural domains, including (1) N-terminal myristoylation and palmitoylation sites that allow association with the plasma membrane; (2) an Src homology (SH)3 domain that associates with proline-rich sequences; (3) an SH2 domain that binds proteins that contain phosphotyrosine; and (4) a carboxy-terminal negative regulatory site. Their catalytic activity is regulated by the balance between the actions of kinases and phosphatases. Activity is repressed by phosphorylation of a conserved carboxy-terminal tyrosine, and dephosphorylation by the phosphatase CD45 is critical for the initiation of TCR-mediated signal transduction. In addition, autophosphorylation of other tyrosines within the kinase domain enhances

catalytic activity. Lck is physically and functionally associated with CD4 and CD8; 50% to 90% of total Lck molecules is associated with CD4, and 10% to 25% is associated with CD8. CD4 and CD8 physically associate with the TCR/CD3 complex during antigen stimulation as a result of their interaction with class II MHC and class I molecules, respectively, and thus they enhance TCR-mediated signals by recruiting Lck to the TCR complex. Lck phosphorylates the CD3 chains, TCRζ, ZAP-70, phospholipase C-γ1 (PLC-γ1), Vav, and Shc. Fyn binds TCRζ and CD3ε and, although its substrates are less well defined, T cells lacking Fyn have diminished response to TCR signals.[21] Vitamin D, the deficiency of which is linked to various autoimmune disorders, strongly upregulates PLC-γ1 after TCR activation and enhances signaling efficiency.[22] In addition, the SH2 and SH3 domains of Src PTKs can mediate their association with molecules that contain phosphotyrosine and proline, respectively.

Somewhat less information is known about the Csk and Tec PTKs. Csk negatively regulates TCR signaling by phosphorylating the carboxy-terminal tyrosine of Lck and Fyn. Dephosphorylation of this negative regulatory tyrosine is mediated by the transmembrane tyrosine phosphatase CD45. CD45 activity is essential for TCR signaling because CD45-deficient T cells fail to activate by TCR stimulation. The Tec family member Itk is preferentially expressed in T cells. T cells from Itk-deficient mice have diminished response to TCR stimulation. The mechanism by which Itk regulates TCR signaling has not been determined, although recent studies have shown that Itk is an important component of the pathway leading to increased intra-cellular $Ca^{2+}$.

Phosphorylation of the ITAM motifs on the CD3 complex recruits the Syk kinase family member ZAP-70 by its tandem SH2 domains. ZAP-70 is expressed exclusively in T cells and is required for TCR signaling. After TCR stimulation, ZAP-70 is activated by phosphorylation of tyrosine 493 by Lck.[23] Loss-of-function hypomorphic alleles of ZAP-70 result in reduced TCR signaling and a propensity for autoimmune phenomena such as rheumatoid factor production.[24]

## Adaptor Proteins

Phosphorylation of tyrosine residues in ITAMs and PTKs after TCR stimulation creates docking sites for adaptor proteins. Adaptor proteins contain no known enzymatic or transcriptional activities but mediate protein-protein interactions or protein-lipid interactions. They function to bring proteins in proximity to their substrates and regulators, as well as sequester signaling molecules to specific subcellular locations. The protein complexes that are formed can function as either positive or negative regulators of TCR signaling, depending on the molecules they contain.

Two critical adaptor proteins for linking proximal and distal TCR signaling events are SH2-domain–containing leukocyte protein of 76 kD (SLP-76) and Linker for activation of T cells (LAT; see Figure 12-4). Loss of these adaptor proteins has profound consequences for T cell development. Mice deficient for LAT or SLP-76 manifest a block in T cell development at the $CD4^{-}8^{-}$ $CD25^{+}CD44^{+}$ stage. LAT is constitutively localized to lipid rafts and, after TCR stimulation, is phosphorylated on tyrosine residues by ZAP-70. Phosphorylated LAT then recruits proteins that contain SH2 domain, including PLCγ1, the p85 subunit of phosphoinositide-3 kinase, IL-2–inducible kinase (Itk), and the adaptors Grb2 and Gads. Because the SH3 domain of Gads is constitutively associated with SLP-76, this brings SLP-76 to the complex, where it is phosphorylated by ZAP-70. SLP-76 contains three protein-binding motifs: tyrosine phosphorylation sites, a proline-rich region, and an SH2 domain. The N-terminus of SLP-76 contains tyrosine residues that associate with the SH2 domains of Vav, the adaptor Nck, and Itk. Vav is a 95 kDa protein that acts as a guanine nucleotide exchange factor for the Rho/Rac/cdc42 family of small G proteins. The complex of LAT, SLP-76/Gads, PLCγ1, and associated molecules results in the full activation of PLCγ1 and activation of Ras/Rho guanosine triphosphatases (GTPases) and the actin cytoskeleton.

In addition to acting as positive regulators for TCR signaling, adaptors can also mediate negative regulation. As described previously, the activity of the Src family kinases is regulated by the interaction of kinases (Csk) and phosphatases (CD45) specific for inhibitory C-terminal phosphotyrosine, which is determined by the subcellular localization of these regulatory molecules. A second mechanism by which adaptor proteins can negatively regulate TCR stability is through regulation of protein stability. Proteins can be targeted for degradation by the conjugation of the 76–amino acid protein ubiquitin to lysine residues via a series of enzymatic reactions by E1, E2, and E3 ubiquitin ligases. Cbl-b, c-Cbl, ITCH, and GRAIL are E3 ligases, and mice lacking these proteins manifest T cell hyperproliferation and autoimmune phenotypes. For example, Cbl-b binds and ubiquitinates ZAP70, resulting in its degradation and reduced TCR signaling.[25]

## Downstream Transcription Factors

The aforementioned signaling events couple TCR stimulation to downstream pathways that culminate in changes in gene transcription that are required for proliferation and effector function (see Figure 12-4). One of the best-characterized genes induced after T cell activation is the T cell growth factor IL-2. Transcription of the *IL2* gene is regulated in part by the transcription factors AP-1, nuclear factor of activated T cells (NFAT), and nuclear factor (NF)-κB, all of which are activated after TCR stimulation. Proximal signaling events lead to the activation of Ras and PLCγ.[26] Ras initiates a cascade of kinases including Raf-1, MEK, and the MAP kinase ERK, which leads to the production of the transcription factor Fos. Ligation of the co-stimulatory molecule CD28 results in the activation of another member of the MAP kinase family, c-Jun N-terminal kinase (JNK), and phosphorylation of the transcription factor c-Jun. c-Jun and Fos associate to form AP-1. PLCγ hydrolyzes membrane inositol phospholipids to generate phosphoinositide second messengers including inositol 1,4,5-trisphosphate ($IP_3$) and diacylglycerol. $IP_3$ stimulates the mobilization of calcium from intra-cellular stores. Diacylglycerol activates protein kinase C (especially PCKθ in T cells) and, along with CARMA, connects with the NF-κB pathway.[26]

Increased intra-cellular calcium is central to many forms of cellular activation. Calcium activates the calcium/calmodulin-dependent serine phosphatase, calcineurin,

which dephosphorylates NFAT.[27] Dephosphorylated NFAT translocates to the nucleus and, together with AP-1, forms a trimolecular transcription factor for the *IL2* gene. The immunosuppressive agents cyclosporin-A and FK-506 specifically inhibit the calcium-dependent activation of calcineurin, thereby blocking activation of NFAT and the transcription of NFAT-dependent cytokines such as IL-2, IL-3, IL-4, and granulocyte-macrophage colony-stimulating factor (GM-CSF). Recently it has been appreciated that differences in the amplitude and duration of calcium signals mediate different functional outcomes. Although high spikes of calcium are easily measured in lymphocytes during the first 10 minutes after antigen stimulation, sustained low-level calcium spikes over a few hours are necessary for full activation. These latter more subtle calcium fluxes appear to be controlled by cyclic adenosine phosphate (ADP)-ribose and ryanodine receptors.[28] Selective inhibitors exist for these molecules, opening the potential for new specific blockers of T cell activation.

A surprising discovery was the observation that caspase activity, particularly of caspase-8, is required to initiate T cell proliferation and activation of NF-κB.[29,30] Previously the role of caspases had been confined to apoptosis. However, it is now appreciated that after TCR ligation, caspase-8 is activated and forms a complex that includes the NF-κB adaptor proteins CARMA1, Bcl-10, and MALT1.[31]

T cell development, proliferation, differentiation, and apoptosis are regulated by small RNA noncoding molecules called microRNAs (miRNAs). These miRNAs bind to their target mRNAs, resulting in mRNA degradation and reduced protein expression. miRNAs modulate TCR signal strength and apoptosis during thymocyte development and have a critical role in the differentiation of $CD4^+$ T cell subsets, particularly T regulatory cells (Tregs).[32] Known targets for miRNAs include IL-2, IL-10, FOXP3, FasL, Jak1, Bcl-2, and Bim. miRNAs also regulate ERK and JNK signaling. Dysregulation of miRNA expression profiles is linked to autoimmune diseases, including RA and systemic lupus erythematosus (SLE).[32] The therapeutic potential of miRNA modulation has been tested in a murine model of lupus, where restoration of miRNA was shown to prevent progression of SLE.[32]

## Co-Stimulation

Signal 2 is mediated either by growth factor cytokines or through a co-stimulatory molecule, of which the prototype is CD28 interacting with CD80 (B7-1) or (CD86) (B7-2). CD28 is a disulfide-linked homodimer constitutively expressed on the surface of T cells. Virtually all murine T cells express CD28, whereas in human T cells, nearly all $CD4^+$ and 50% of $CD8^+$ cells express CD28. The $CD28^-$ subset of T cells appears to represent a population that has undergone chronic activation and can manifest suppressive activity. Increased levels of $CD28^-$ T cells have been reported in several inflammatory and infectious conditions, including granulomatosis with polyangiitis (GPA), RA, cytomegalovirus (CMV), and mononucleosis.[33-35] The cytoplasmic domain of CD28 has no known enzymatic activity but does contain two SH3 and one SH2 binding sites. CD28 interacts with $PI_3$ kinase and GRB2 and promotes JNK activation, as previously noted. CD28 ligation alone does not transmit a proliferative response to T cells, but in conjunction with TCR engagement, it augments IL-2 production at the level of both transcription and translation. It also increases the production of other cytokines, including IL-4, IL-5, IL-13, IFN-γ, and TNF, as well as the chemokines IL-8 and RANTES. An additional member of the CD28 superfamily, inducible T cell co-stimulator (ICOS), is expressed on activated T cells and binds to B7-related protein (B7RP1) on APCs.[36] It is believed to be important particularly to $CD4^+$ Th2 cells. Several products are in development to interrupt ICOS signaling and are in early phases of testing for SLE.

The ligands for CD28, CD80 (B7-1), and CD86 (B7-2) are expressed in a restricted distribution on B cells, dendritic cells, monocytes, and activated T cells. CD80 and CD86 have similar structures but share only 25% amino acid homology. They each contain rather short cytoplasmic tails that may signal directly and bind to CD28 with different avidities. Increased levels of soluble co-stimulatory molecules CTLA-4, CD28, CD80, and CD86 have been reported in patients with SLE and correlate with disease activity.[37] Recent studies with biologic therapies have revealed alterations in co-stimulatory molecules. For example, B cell depletion with anti-CD20 (rituximab) can lead to reduced CD4 T cell expression of CD40L, a B cell co-stimulatory molecule.[38]

## The Immunologic Synapse

Antigen-specific interaction between the T cell and APC results in the formation of a specialized contact region called the immunologic synapse or supramolecular activation cluster (SMAC)[39] (Figure 12-5). Synapse formation is an active, dynamic process that requires specific antigen to drive synapse formation; TCR:MHC interaction alone is not sufficient. The synapse also overcomes the obstacles resulting from interactions of tall molecules (e.g., ICAM-1, LFA-1, and CD45) to promote T cell/APC contact that is mediated by short molecules (e.g., TCR, MHC, CD4, and CD8). Two stages of assembly have been described. During the nascent stage, cell adhesion molecules such as ICAM-1 on APC and LFA-1 on T cells make contact in a central zone, surrounded by an annulus of close contact between MHC and TCR.[39] Within minutes the engaged TCR migrates to the central area, resulting in a mature synapse in which the initial relationships are reversed—the central area (CSMAC) now contains TCR, CD2, CD28, and CD4 and is enriched for Lck, Fyn, and PKC-θ. Surrounding the central domain is a peripheral ring (PSMAC) that contains CD45, LFA-1, and associated talin. T cell activation leads to compartmentalization of activated TCR and TCR signaling molecules to plasma membrane microdomains called "rafts."[40] Rafts are composed primarily of glycosphingolipids and cholesterol and are enriched in signaling molecules, actin, and actin-binding proteins. Src family kinases, Ras-like G proteins, LAT, and phosphatidylinositol-anchored membrane proteins have all been shown to localize to raft domains.

Full T cell activation requires engagement of a minimum of approximately 100 to 200 MHC/peptide molecules on an APC, which can serially stimulate 2000 to 8000 TCRs. It has been estimated that naïve T cells also require a sustained signal for 15 to 20 hours to commit to proliferation.

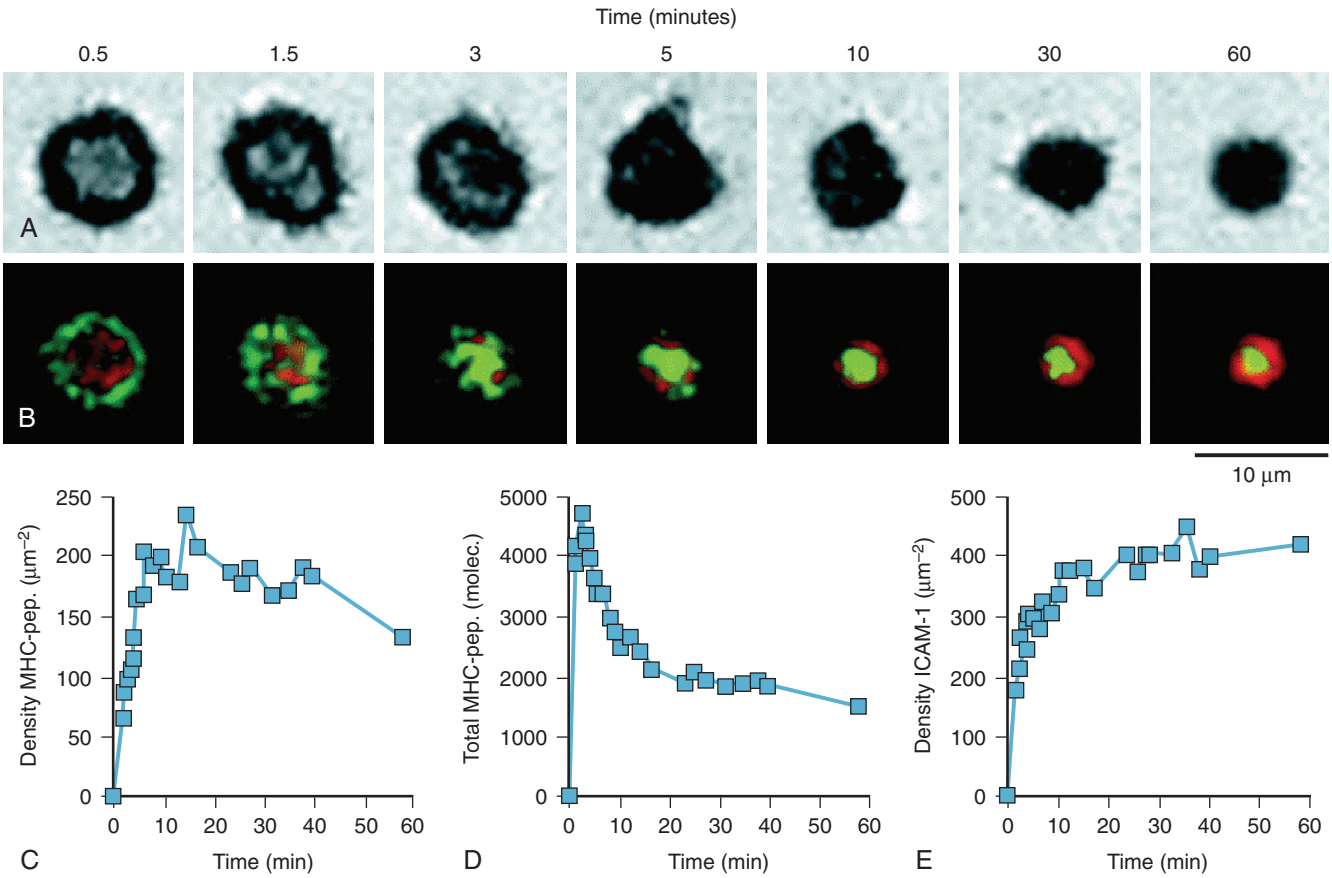

**Figure 12-5** Formation of the immunological synapse. **A,** Contact areas of T cells shown over the time points are indicated as dark gray against a light background. **B,** Images containing Oregon green $E^k$-antigen (mouse cytochrome peptide 88-103) and Cy5 intercellular adhesion molecule-1 (ICAM-1). **C,** Density of accumulated $E^k$-MCC88-103. **D,** Total accumulated $E^k$-MCC88-103. **E,** Density of accumulated ICAM-1. MHC, Major histocompatibility complex. *(From Grakoui A, Bromley SK, Sumen C, et al: The immunological synapse: a molecular machine controlling T cell activation.* Science *285:221-227, 1999.)*

T cells face a number of obstacles to achieving full activation, including the small physical size of the TCR and MHC molecules compared with other cell surface molecules, the low affinity of TCR for MHC/peptide complex, and the low number of MHC molecules present on the APCs that contain the antigenic peptide. The immunologic synapse may provide the mechanism for overcoming these barriers and achieving the duration of TCR stimulation necessary to commit the cell to proliferation.[39] The spatial organization of the synapse juxtaposes the membranes of the APC and T cell, facilitating the interaction of the TCR and MHC/peptide complex. The available MHC/peptide complexes and TCRs are concentrated at the site of contact via actin cytoskeleton–mediated transport. The multistep process of mature synapse formation may also enable the T cell to discriminate among the potential antigen-containing MHC/peptide complexes it encounters on the APC cell surface. It has been shown that co-stimulatory signals may contribute to synapse formation by initiating the transport of membrane rafts containing the kinases and adaptor molecules required for TCR signaling to the site of contact.[41]

It was recently observed that certain $CD4^+$ T cells can respond to the citrullinated peptides[42] and that such citrullination of peptides is induced by autophagy, a reprocessing of organelles during cellular stress. In addition, class II human leukocyte antigen (HLA)-DR4 molecules, a haplotype associated with RA, are very efficient at presenting citrullinated peptides to $CD4^+$ T cells.[42] This may begin to explain the mystery of why HLA-DR4 is associated with RA.

## Tolerance and Control of Autoreactive T Cells

The immune system is constantly confronted by the problem of how to ensure that T cells are activated only under conditions in which a true need exists for a response to a foreign pathogen and not merely a self-component. As with many biologic filters, thymic negative selection is not 100% efficient, and not all self-reactive T cells are eliminated. Hence, a variety of fail-safe mechanisms are engaged to suppress the ability of these errant T cells to undergo premature clonal expansion. This process is partly regulated by the requirement of two distinct signals from separate molecules to be coordinately triggered in order for T cell activation and proliferation to proceed. If only one of the signals is received, the T cell will not proliferate and will actually enter a nonresponsive state known as tolerance or anergy.

The anergy that results from the absence of a CD28 co-stimulatory signal manifests as a failure to fully couple the TCR signal to the Ras/MAP kinase pathway and

consequent AP-1 transcriptional activity. An additional method of provoking an incomplete TCR signal and unresponsiveness is to make amino acid substitutions in the recognized peptide antigen. These so-called "altered peptide ligands" cause a suboptimal phosphorylation of TCRζ and consequent inefficient recruitment of ZAP-70.

Additional members of the CD28 family serve as inhibitory molecules, many of which have been targeted for therapeutic intervention of autoimmune disorders. Cytolytic T lymphocyte–associated protein 4 (CTLA-4) also binds to CD80 and CD86 with 20-fold higher affinity than CD28. Unlike CD28, CTLA-4 is expressed only transiently after T cell activation and confers an inhibitory signal for T cell proliferation.[43] In this capacity, CTLA-4 functions to limit T cell clonal expansion induced by CD28. The consequences of the loss of this negative regulation are striking. The genetic deletion of the *Ctla4* gene in mice results in enormous uncontrolled T cell expansion and an autoimmune diathesis.[44] *Ctla4* was also identified as a genetic risk factor in RA.[45] CTLA4-Ig (abatacept) has been licensed in the United States for treatment of RA and has been used in clinical trials for a variety of autoimmune disorders.

Programmed cell death 1 (PD-1) is another member of the CD28 family that possesses an immunoreceptor tyrosine–based inhibiting motif (ITIM) within its cytoplasmatic tail that associates with the tyrosine phosphatase SHP2.[46] PD-1 does not bind the CD28/CTLA-4 ligands, CD80 or CD86, but rather binds to PD-L1 and PD-L2. PD-L1 is expressed by both lymphoid (e.g., regulatory $CD4^+CD25^+$ T cells, inflammatory macrophages) and nonlymphoid tissues such as heart, placenta, lung, and pancreas. PD-L2 expression is more confined to macrophages and dendritic cells.[47] Ligation of PD-1 on T cells leads to cell cycle arrest. Treatment of mice with a blocking antibody to PD-L1 caused virus-specific $CD8^+$ T cells to undergo marked expansion.[46,47] The fact that many tumors also express PD-L1 enhances the interest in reversing suppression of immune responses during infection and tumorigenesis. The finding that lupus-like arthritis and glomerulonephritis develop in PD-1–deficient mice enhances interest in manipulating PD-1 for therapeutic purposes.[48] The clinical trials of anti–PD-1 and anti–PD-L1 therapy for a variety of tumors will warrant careful observations for potential autoimmune adverse effects.

Chronic exposure to certain inflammatory cytokines, most notably TNF, can also induce anergy. It has been appreciated for some time that T cells from rheumatoid synovium manifest profound deficiencies of proliferation and cytokine production,[49] and TNF is one of the major cytokines detectable in rheumatoid synovial fluid. Further studies demonstrated that chronic exposure of T cell clones to TNF for 10 to 12 days suppressed proliferative and cytokine responses to antigen by as much as 70%.[50] Furthermore, a single administration of anti-TNF receptor monoclonal antibody to patients with RA rapidly restored the response of peripheral T cells to mitogens and recall antigens.[50] Similar observations have been made in TCR transgenic mice after TNF exposure.[51] The observation that chronic TNF exposure inhibited calcium responses after TCR ligation[51] supports the view that TNF may uncouple TCR signaling. Conceivably, other members of the TNF family may invoke similar T cell anergy.

An additional negative regulator for T cells is the B lymphocyte–induced maturation protein 1 (Blimp-1), which was initially identified in B lymphocytes. Blimp-1–deficient mice manifest augmented levels of peripheral effector T cells and experience severe colitis as early as 6 weeks of age.[52] Blimp-1 mRNA expression increases with TCR stimulation, and Blimp-1–deficient T cells manifested enhanced proliferation and produced more IL-2 and IFN-γ after activation.[52]

Another layer of regulation occurs via a phenotypically defined subpopulation of $CD4^+CD25^+$ $FoxP3^+$ Tregs that has the ability to inhibit antigen-induced proliferation.[53] This subset is expressed in the periphery at a low frequency and appears to be at least partly thymic-dependent. The latter point may be of interest because it suggests that the absence of Tregs after day 3 thymectomy may be involved with the subsequent development of autoimmune disease in these animals.[54] Indeed, diminished levels of $CD4^+CD25^+$ $FoxP3^+$ regulatory T cells have been observed in other autoimmune syndromes, and the transfer of Tregs to autoimmune mice has shown some alleviation of symptoms. The production of TGF-β and IL-10, and possibly expression of CTLA-4, appear to be critical to the suppressive activity of Tregs.[55] This area of research is very active because of the potential therapeutic implications for autoimmune diseases and their possible role in generating IL-17–producing $CD4^+$ T cells (Th17; see later discussion).[56] In this regard, recent studies to treat type 1 diabetes by increasing Treg number and function using anti-CD3 antibody or IL-2 are promising.[57] In addition, a recent genetic analysis of risk loci for RA identified the greatest enrichment of trimethylation of histone H3 at lysine 4 of RA risk factors in Tregs, out of 34 cell types studies, further supporting a role for Tregs in the pathogenesis of RA.[58]

## T CELL SUBSETS

### $CD4^+$ Helper and $CD8^+$ Cytolytic T Cells

αβ T cells can be subdivided into two main subsets based on their recognition of peptides presented by class I or class II MHC molecules and their respective expression of CD8 or CD4. $CD4^+$ and $CD8^+$ T cells have different functions and recognize antigens derived from different cellular compartments. The peptides presented by class I MHC molecules are produced by the proteasome[59] and can be derived from either self-proteins or intra-cellular foreign proteins, as might occur during viral infection. Class II MHC–bound peptides are derived largely from extra-cellular infectious agents or self–cell surface proteins that have been engulfed and degraded in the lysosomal complex.

$CD4^+$ T cells express a variety of cytokines and cell surface molecules that are important to B cell proliferation and immunoglobulin production and $CD8^+$ T cell function. After antigen stimulation, $CD4^+$ T cells differentiate into different classes of effector T cells that are identified by their cytokine profiles, including T helper 1 (Th1) Th2, Th17, follicular helper T cells (Tfh; described later), and Treg cells, which were previously described (Figure 12-6). The CD4 molecule is structurally related to immunoglobulins and has an affinity for nonpolymorphic residues on the MHC class II molecule. In this capacity CD4 presumably

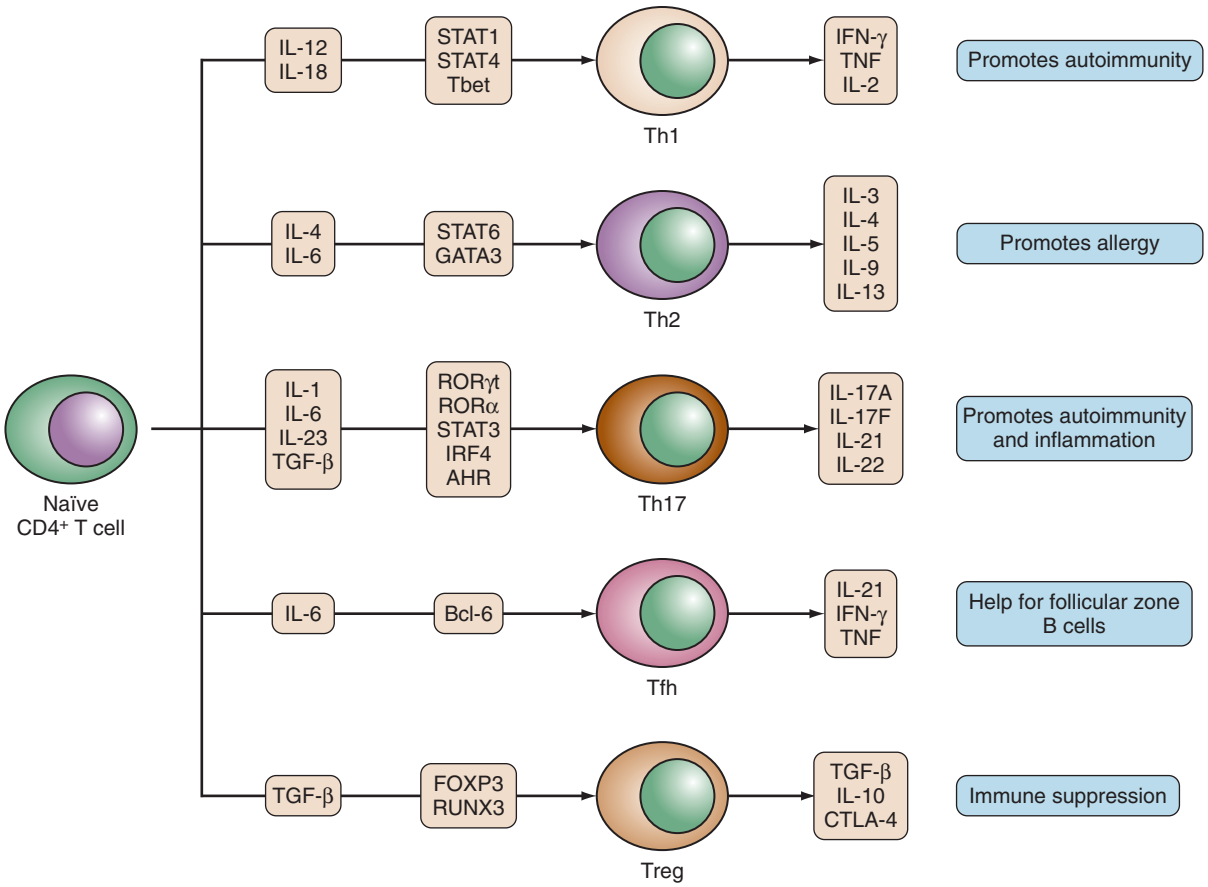

**Figure 12-6** T helper subsets. Naïve CD4 T cells can be polarized into producing particular patterns of cytokines depending upon the cytokine environment in which they develop and the expression of certain transcription factors.

increases the efficiency with which $CD4^+$ T cells recognize antigen in the context of class II MHC molecules, whose expression is restricted to B cells, macrophages, dendritic cells, and a few other tissues during states of inflammation. In addition, the cytoplasmic tail of CD4 binds to Lck and promotes signaling by the TCR as described earlier. However, ligation of CD4 prior to engagement of the TCR renders the T cell susceptible to apoptosis upon subsequent engagement of the TCR.[60] This phenomenon is clinically important in HIV infections in which the gp120 molecule of HIV binds to CD4 and primes the T cell to undergo cell death when later triggered by the TCR. Accelerated apoptosis of $CD4^+$ T cells has been demonstrated in patients with acquired immunodeficiency syndrome (AIDS).[61]

$CD8^+$ T cells are very efficient killers of pathogen-infected cells. Given the ubiquitous expression of class I MHC molecules, mature CTLs can recognize viral infections in a wide array of cells, in distinction to the more restricted distribution of class II molecules. CTLs lyse target cells through the secretion of perforin and granzymes, which induce holes in cell membranes and cleave cellular substrates, respectively, and through the expression of Fas-Ligand and TNF, which induce apoptosis. Similar to CD4, CD8 manifests an affinity for class I MHC molecules, enhances the signaling of CTLs, and also binds Lck by its cytoplasmic tail.

## T Cells in the Innate Immune Response

In addition to the broad array of antigens recognized by αβ T cells, there is growing appreciation that the immune system also contains small subpopulations of T cells that may be specialized to recognize conserved structures that are either uniquely expressed by prokaryotic pathogens or on stressed host cells. These T cells are discussed in detail in Chapter 17. Such common antigenic motifs include bacterial lipoproteins and lipopolysaccharides recognized by Toll-like receptor (TLR)2 and TLR4, respectively, double-stranded RNA from RNA viruses that binds TLR3, and methylated cytosine residues in bacterial CpG sequences, or anti-DNA/DNA complexes that bind to TLR9.[62] TLR expressed by APCs can trigger the release of cytokines and co-stimulatory molecules for T cells. Another family of molecules that likely binds bacterial components is CD1. CD1 structurally resembles class I MHC but contains a deeper and more hydrophobic binding pocket that can accommodate certain lipopeptides and glycolipids. By using such molecular strategies to focus on common and nonpolymorphic molecules, this innate immune response can respond quickly during the early phase of infections. Although it may represent the remnants of an evolutionarily more primitive immune response, it nevertheless provides a very vital early defense system. Among T cells, this function is provided by γδ and natural killer (NK) T cells.

## γδ T Cells

γδ T cells were identified after the serendipitous discovery of rearranged genes while searching for the TCR α chain gene; we did not have pre-existing knowledge of their presence and biologic function.[63] Structurally, the γ chain locus contains at least 14 Vγ region genes, of which six are pseudogenes, each capable of rearranging to any of five Jγ regions and two Cγ regions. The δ-chain genes are nested within the α-chain gene locus between Vα and Jα. There are about six Vδ regions, two Dδ and two Jδ regions, and a single Cδ gene. Transcription of rearranged γ and δ genes begins prior to αβ genes and is apparent on days 15 to 17 of mouse thymus development, after which it declines in the adult thymus. In addition to the ordered appearance of TCR-γδ before TCR-αβ, there is also a highly ordered expression of γ and δ V-region genes during early thymic development, which results in successive waves of oligoclonal γδ T cells migrating to the periphery. The reason for this remarkable regimentation remains unclear.

γδ T cells manifest a number of differences from αβ T cells. γδ T cells are often anatomically sequestered to epithelial barriers or sites of inflammation and frequently manifest cytotoxicity toward a broad array of targets.[64] In contrast to αβ T cells, γδ T cells can respond to antigen directly, without evidence of MHC restriction,[65] or conversely, they can react to MHC molecules without peptide.[66] γδ T cells exit the thymus with a memory-like phenotype and can therefore respond rapidly to their first encounter with antigen. Unlike $CD4^+$ T cells that differentiate into effector subsets after TCR and cytokine signaling, mature γδ T cell subsets already manifest a distinct cytokine profile and includes production of IL-17, IFN-γ, and IL-4.

Human γδ T cell clones, particularly those expressing the Vδ2 gene and derived from peripheral blood of healthy individuals, frequently react to nonprotein components of mycobacteria.[67] These components have been identified as nucleotide triphosphates,[68] prenyl pyrophosphate,[69] and alkylamines.[70] These molecules are, respectively, subunits in DNA and RNA, substrates in lipid metabolism for the synthesis of farnesyl pyrophosphate, and products of pathogenic organisms. These phosphate-containing nonpeptides can be found in both microbial and mammalian cells. This finding suggests that γδ cells may recognize a class of antigens shared by a number of pathogens, as well as by damaged or transformed mammalian cells, and may provide insight into the role of γδ cells in infection and their accumulation at sites of inflammation. Another subpopulation of γδ T cells expressing the Vδ1 gene is typically found in the intestine and in inflamed synovial fluid and reacts to the class I MHC–like molecules known as MICA and MICB.[71] Unlike classical class I MHC molecules that are expressed ubiquitously and continuously, MICA and MICB expression appears to be restricted to gut epithelium and occurs only during times of stress, similar to that of a heat shock response.

The contribution of γδ T cells to defense against infection has been examined in mice using a number of pathogens including *Listeria*, *Leishmania*, *Mycobacterium*, *Plasmodium*, and *Salmonella*. All of these studies have shown a moderately protective role for γδ T cells. The cumulative evidence suggests that γδ T cells may not react directly to components of micro-organisms but rather indirectly via the ability of microbial products to stimulate the innate immune response. An example is the γδ T cells in synovial fluid from Lyme arthritis, which are activated by *Borrelia burgdorferi* lipidated hexapeptides of the outer surface proteins that stimulate TLR2.

γδ T cells accumulate at inflammatory sites in autoimmune disorders such as RA,[72] celiac disease,[73] and sarcoidosis.[74] The reason for this accumulation remains an enigma. However, evidence shows that γδ cells can be highly cytolytic toward a variety of tissues, including $CD4^+$ T cells,[75] in part because of their high and sustained expression of surface Fas-ligand.[76] In this regard, deletion of γδ T cells in various autoimmune models often results in exacerbation of disease.[77,78] The presence of γδ T cells can strongly bias the cytokine profiles of the infiltrating $CD4^+$ cells, in some instances toward Th1 profiles,[79] and in others toward Th2.[80]

## Natural Killer T Cells

A minor subpopulation of T cells bearing the NK determinant manifests a curiously restricted TCR repertoire. NK T cells are found within the $CD4^+$ and $CD4^-8^-$ T cell subsets and, in both mouse and human, express a very limited number of TCR-Vβ chains and an invariant α chain (Vα14 in mice and Vα24 in humans).[81] Furthermore, most NK T cells are restricted in their response to a monomorphic class I MHC–like molecule, CD1d. Crystallographic analysis of CD1d has shown that it contains a deeper groove than traditional MHC molecules and is highly hydrophobic, conferring a preference for binding lipid moieties. Originally the sea sponge sphingolipid, α galactosylceramide, was the only known CD1d ligand. Now both endogenous and bacterial (*Sphingomonas* and *B. burgdorferi)* sources of CD1d-binding sphingolipids have been identified.[82,83] This may represent another type of innate T cell response whereby bacterial lipids or lipopeptides may be presented to NK T cells to provoke a rapid early immune response.

The potential importance of NK T cells in autoimmune disease stems from their rapid production of high levels of certain cytokines, particularly IL-4 and IFN-γ.[81] In this capacity, the IL-4 response may be important for modulating inflammatory responses dominated by Th1 infiltrates. This phenomenon has been noted in the nonobese diabetic (NOD) mouse model of diabetes, which has reduced levels of NK T cells.[84] Adoptive transfer of NK T cells into NOD mice blocks the onset of diabetes.[85] A study extended this observation to human type 1 diabetes. The NK T cells of diabetic individuals produced more IFN-γ and less IL-4 than did the NK T cells of their unaffected siblings.[86] NK T cells have also been reported to be the predominant $CD4^+$ T cell in the airways of patients with asthma.[87] Thus, this minor population of T cells may play a pivotal role in early innate responses to certain infections and also in the regulation of inflammatory sites.

## Naïve Versus Memory T Cells

$CD4^+$ and $CD8^+$ T cells emigrate from the thymus bearing a naïve phenotype. Naïve T cells produce IL-2 but only low levels of other cytokines and as such provide little B cell help. Naïve T cells express high levels of Bcl-2 and can survive for extended periods without antigen but require the

presence of MHC molecules. Naïve T cells circulate from the blood to lymphoid tissues of the spleen and lymph nodes, where antigen, APCs, T cells, and B cells are concentrated. Particularly important in this environment as APCs are dendritic cells, which can migrate from other areas of the body such as the skin and are highly efficient at processing and presenting antigen to T cells (see Chapter 9). Dendritic cells express high and constitutive levels of class II MHC and co-stimulatory molecules CD80 (B7-1) and CD86 (B7-2) that are critical to promote proliferation of naïve T cells. In this capacity dendritic cells are particularly adept at promoting clonal expansion of antigen-specific T cells. The development of antigen peptide/MHC tetramer technology has led to direct quantitation of antigen-specific CD8 T cells using flow cytometry. Viral-specific CD8 T cells have an incredible ability to expand after infection, from levels that are undetectable to nearly 50% of the CD8 population, representing a nearly 1000-fold increase in only a few days.[88]

During the process of clonal expansion of naïve T cells and their differentiation into effector and eventually memory T cells, as many as 100 genes are induced. These genes are manifested primarily as increased expression of certain surface molecules involved with cell adhesion and migration (CD44, ICAM-1, LFA-1, α4β1 and α4β7 integrins, and the chemokine receptor CXCR3), activation (CD45 change from high molecular weight CD45RA to lower molecular weight CD45RO isotype), cytokine production (increased production of IFN-γ, IL-3, IL-4, and IL-5) and death receptors (e.g., Fas/CD95) (Table 12-1). More transiently induced are CD69, the survival factor Bcl-xL, and the high-affinity growth factor IL-2 receptor α chain (CD25). Survival of effector T cells to the memory stage is partly dependent upon the cytokines IL-7 and IL-15.[89]

The concept of immune memory has existed since the first successful vaccinations by Jenner for smallpox. A useful memory T cell marker in the murine system is CD44, the hyaluronate receptor. Surface CD44 is low on mature single positive T cells as they emerged from the thymus, but its expression is upregulated upon the first encounter with antigen stimulation in the periphery. Expression of the IL-7 receptor identifies a subset of effector T cells that are destined to become memory T cells. Several other markers have been shown to change upon primary antigenic stimulation. Most notable for human T cells is CD45, in which an isoform known as CD45RA is expressed on naïve T cells, whereas CD45RO expression characterizes memory T cells (Table 12-1). Using these markers, it has been possible to identify a variety of differences between naïve and memory T cells. Activation of memory T cells appears to be more efficient than that of naïve T cells and appears not be absolutely dependent upon co-stimulation. Memory T cells are also able to migrate to nonlymphoid tissues such as lung, skin, liver, and joints.[90] Particularly interesting have been recent reports that the metabolic state of an effector T cell may profoundly affect which T cells survive to the memory state. After T cell activation they rapidly activate glycolysis, which provides many of the precursors need for the synthesis of nucleic acids, amino acids, and lipids needed for proliferation and effector T cell function. However, the survival of T cells to the memory stage requires the return to a relatively nonglycolytic state of fatty acid metabolism and mitochondrial oxidative phosphorylation. Thus, improved survival of memory T cells was conferred by agents such as rapamycin and metformin, which inhibit anabolic glycolytic metabolism and promote catabolic fatty acid metabolism.[91]

## T Helper Subsets

CD4 T cells can be further subdivided on the basis of their cytokine profiles (see Figure 12-6). Th1 cells participate in cell-mediated inflammatory reactions, activate macrophages, and produce IL-2, TNF, and IFN-γ. Th2 cells produce IL-4, IL-5, IL-6, and IL-10. IL-4 and IL-5 are important B cell growth factors.[92] In addition, IL-4 promotes B cell secretion of immunoglobulin (Ig)$G_1$ and IgE, whereas IFN-γ drives $IgG_{2a}$ production. Because Th1 and Th2 cells mediate different functions, the type of response generated can influence susceptibility to disease. These

**TABLE 12-1** Surface Markers on Naïve and Memory T Cells

| Molecule | Other Designation | Molecular Weight (kDa) | Characteristic | EXPRESSION | |
|---|---|---|---|---|---|
| | | | | Memory | Naïve |
| CD58 | LFA-3 | 45-66 | Ligand for CD2 | ++ | + |
| CD2 | T11 | 50 | Alternative activation pathway | +++ | ++ |
| CD11a/CD18 | LFA-1 | 180-195 | Receptor for ICAM-1, ICAM-2, ICAM-3 | +++ | ++ |
| CD29 | | 130 | β chain of β1 (VLA) integrins | ++++ | + |
| CD45RO | | 220 | Isoform of CD45 | ++++ | – |
| CD45RA | | 80-95 | Isoform of CD45 | – | ++++ |
| CD44 | Pgp-1 | 90 | Receptor for hyaluronic acid | +++ | ++ |
| CD54 | ICAM-1 | 120 | Counterreceptor for LFA-1 | + | – |
| CD26 | | 40 | Dipeptidyl peptidase IV | + | – |
| CD7 | | Multichain complex | T cell lineage marker | +/– | ++ |
| CD3 | | | Part of TCR complex | + | + |

CD, Cluster of differentiation; ICAM, intercellular adhesion molecule; LFA, leukocyte function–associated antigen; TCR, T cell antigen receptor; VLA, very late activation antigen.

patterns have been best characterized during chronic infections. In general, a Th1 response helps eradicate intracellular micro-organisms, such as *Leishmania major* and *Brucella abortus*,[93] whereas a Th2 cell response can better control extra-cellular pathogens, such as the helminth, *Nippostrongylus braciliensis*.[94] The cytokine profiles of Th1 and Th2 cells are mutually inhibitory, such that the Th1 cytokine IFN-γ or IL-12 from APC suppresses Th2 responses and augment Th1 cytokine gene expression, whereas the Th2 cytokines IL-4, or IL-6 from APCs, promote the opposite pattern. Polarization of the cytokine environment also occurs at the sites of inflammation in many autoimmune syndromes. Th2 skewing has been observed in models of SLE where increased levels of immunoglobulins and autoantibodies are typical, as well as in chronic allergic conditions such as asthma.[95] Frequently, however, the infiltrating lymphocytes exhibit a bias toward Th1 cytokines. This bias occurs with brain-infiltrating lymphocytes in multiple sclerosis and its animal model experimental allergic encephalomyelitis (EAE),[96] β islet lymphocytes in diabetes,[97] and synovial lymphocytes in inflammatory arthritides.[98] Unlike the beneficial effects of Th1 responses during infections, these same cytokines can be quite deleterious in autoimmune disorders. Thus therapies based on inhibition of certain Th1 cytokines have been of considerable interest and often ameliorative, such as TNF inhibitor treatment of RA.[99] Several cytokines can have pleiotropic effects, and predicting the effects of modulating their levels can be complex. For example, despite the tendency of IL-6 to promote a Th2 cytokine profile, nonetheless, blocking IL-6 is beneficial in RA.[100]

A subset of IL-17–producing $CD4^+$ T cells (Th17) has emerged as being critical for promoting a variety of autoimmune disorders. Th17 cells are regulated by the transcription factor RORγt and can be broadly divided into two groups: first, host protective cells that express both IL-17 and IL-10 and are activated by TGF-β and IL-6, and second, a highly inflammatory population that expresses IL-17, IL-22, and IFN-γ and is activated by IL-23 and IL-1β.[101,102] IL-22 has important functions at mucosal surfaces in host defense, as well as in wound repair. It is produced primarily by Th17 $CD4^+$ T helper cells and innate lymphocytes but acts only on nonhematopoietic stromal cells, particularly epithelial cells, keratinocytes, and hepatocytes.[102] In addition to strengthening epithelial barrier functions, excessive IL-22 can evoke pathologic conditions, such as psoriasis-like skin inflammation.[101] Injections of IL-23 into skin produced increased IL-17 in the epidermis and inflammatory lesions that resembled psoriasis.[103] Th17 $CD4^+$ cells are increased in human psoriatic plaques,[103] in RA synovial fluid, and in multiple sclerosis.[104] Genome-wide association studies (GWAS) have linked genes involved with Th17 cells in RA and Crohn's disease.[102] In addition, inhibitors of Th17 cells have been described that are likely to be used clinically.[105] An additional CD4 T helper subset is found in B cell follicles of secondary lymphoid organs because of their expression of the B cell follicle homing receptor CXCR5.[106] These Tfhs facilitate B cell activation and germinal center formation through expression of CD40L, IL-4, and IL-21. Dysregulation of Tfh function can result in autoantibody production and systemic autoimmunity.[107] Finally, $CD4^+FoxP3^+$ Tregs have already been described earlier.

## Molecular Mimicry

Perhaps the oldest concept in autoimmune mechanisms is that of molecular mimicry, the notion that the response of the immune system to a foreign substance may provoke cross-reactivity to a self-protein. This concept is best established in rheumatic heart disease, where a B cell antibody response to a group A streptococcal cell wall component can precipitate a cross-reactivity to cardiac myosin. Similarly for T cells, investigators used the peptide sequence of myelin basic protein (MBP) recognized by specific T cell clones from patients with multiple sclerosis to search a database of infectious agents. Some of the candidate sequences obtained were able to stimulate the MBP-reactive T cell clones,[108] which suggested for the first time that T cells responding to an infectious agent might manifest cross-reactivity to self-peptides. Another example is one of the outer surface proteins of *B. burgdorferi* known as OspA, which may trigger a cross-reactive T cell response.[109] A T cell immunodominant peptide of OspA was identified in a subset of HLA-DR4 patients who are more resistant to antibiotic treatment and manifest an antibody and a T cell response to OspA.[110] Using a sequence algorithm to identify homologous peptides that bind the DR4 pocket, a sequence in LFA-1 was identified that bound DR4 and stimulated a T cell response from these OspA-reactive patients.[109] The technology of peptide/MHC tetramers previously discussed will enable investigators to determine whether a given subpopulation of T cells within an inflammatory synovium might manifest dual specificity for both a foreign pathogen and a cross-reacting self-protein.

## Death of T cells

The rapid removal of the effector T cells after clearance of the infection is as important as the initial clonal expansion of responding T cells for the health of the organism. Failure to clear activated lymphocytes increases the risk of cross-reactivity with self-antigens and a sustained autoimmune reaction. To ensure that resolution of an immune response occurs rapidly, a number of processes promote active cell death of clonally expanded T cells. One means to control T cell proliferation is through limited availability of growth factors. Upon activation, T cells express receptors for various growth cytokines for approximately 7 to 10 days but only produce cytokines for a more limited period, which results in an unstable situation in which T cells tend to outgrow the availability of growth cytokines. For example, T cells expressing IL-2R in the absence of IL-2 will rapidly undergo programmed cell death. Another method is restimulation of TCR on actively dividing T cells, which triggers a death cascade known as activation-induced cell death (AICD).

The discovery of a family of death receptors expressed by T cells elucidated an additional regulatory process. These molecules are described more extensively in Chapter 28, Cell Survival and Death in Rheumatic Diseases, and will only be discussed here as they relate to T cell function. The best described of these is Fas (CD95). Both Fas-deficient mice and humans bearing Fas mutations (Canale-Smith syndrome)[111] manifest a profound lymphadenopathy accompanied by an autoimmune diathesis, which underscores the

importance of efficiently removing T cells after their activation. Nearly all cells have some level of surface Fas, whereas expression of its ligand (FasL) is restricted primarily to activated T cells and B cells. Consequently, regulation of Fas-mediated apoptosis is to a large extent under the governance of the immune system. FasL expression has also been reported for certain components of the eye, the Sertoli cells of the testis, and perhaps some tumors, providing "immune privileged" sites within which immune responses are difficult to initiate.[112] Expression of FasL by these nonlymphoid cells is thought to prevent immune responses at sites where such inflammation might cause tissue damage. During T cell activation, expression of FasL is rapidly induced, and these T cells readily kill Fas-sensitive target cells.

The sequence of T cell activation followed by cell death is graphically displayed after the administration to mice of bacterially or virally derived compounds called *superantigens*. Superantigens activate T cells by directly cross-linking class II MHC molecules with particular β-chain V families of the TCR (see Figure 12-2A). The superantigen staphylococcal enterotoxin B (SEB) strongly activates $V\beta8^+$ T cells.[113] This activation initiates a rapid expansion of $V\beta8^+$ T cells over 2 to 3 days followed by an equally rapid loss of these cells, such that by day 7 very few $V\beta8^+$ T cells remain. A similar process of T cell activation occurs in the human disease toxic shock syndrome in which a related staphylococcal toxin TSST stimulates the expansion of $V\beta2^+$ T cells.[114] The devastating illness that results from this profound activation of a large proportion of T cells underscores the need to rapidly eliminate activated T cells. At least some of the damage in toxic shock syndrome likely results from the extensive T cell expression of FasL and TNF, particularly in certain tissues such as the liver. Hepatocytes are exquisitely sensitive to damage by these ligands. Activation of T cells leads to homing to the liver, and administration of antigen to TCR transgenic mice can yield a syndrome resembling autoimmune hepatitis.[115] Thus certain autoimmune disorders may result from the death or damage of "innocent bystander" cells as a consequence of the migration of activated T cells to an organ and nonspecific damage due to the expression of FasL family members. Proapoptotic members of the Bcl-2 family, Bim, Bad, and Bax, appear to regulate death in vivo from cytokine withdrawal or after acute foreign antigen stimulation, as with certain infections.[116] These molecules are related to the cell survival molecule Bcl-2 but are more truncated, containing only the BH3 domain of Bcl-2, hence their designation as the "BH3-only" family. They function as sentinels within the cell in that they are attached to various cytoskeletal proteins and organelles and sense cellular damage. If damage occurs they are released from these sequestered areas and migrate to the mitochondria to inhibit the survival function of Bcl-2.[116] By contrast, Fas serves to eliminate T cells after chronic TCR stimulation, such as that which occurs in homeostatic proliferation or chronic infections.[117,118]

## T Cells at Sites of Inflammation

The observation that T cells infiltrate target organs in autoimmune diseases such as RA, type 1 diabetes mellitus, and multiple sclerosis quickly led to an analysis of T cell subsets and, more recently, to a more detailed study of the T cell repertoire based on TCR expression. In many of these disorders, the known class II HLA association is paralleled by a predominant, though by no means exclusive, infiltration of $CD4^+$ T cells bearing a broad TCR repertoire.[119] Many of these $CD4^+$ T cells also manifest a Th1-like cytokine profile, as discussed earlier.[96-98] Evidence for the importance of these $CD4^+$ cells derives from numerous studies showing the efficacy of CD4 depletion in animal models of these disorders.[120] A parallel situation has often occurred in humans with these autoimmune diseases who concurrently become infected with HIV. The CD4 depletion occurring during AIDS can actually ameliorate RA.[121] However, the resulting CD8 predominance during HIV infection has also frequently resulted in exacerbation of psoriatic arthritis and Sjögren's syndrome, suggesting the $CD8^+$ subset of T cells may be important in these disorders.[121] Given the aforementioned effect of the metabolic state of T cells on their survival, it will be highly informative in future studies to examine the metabolic state of T cells at sites of autoimmune tissue inflammation versus that observed in secondary lymphoid tissues during infections. Conceivably the cytokine environment of inflamed tissues may confer a metabolic state that favors T cell survival compared with states of infection.

CHAPTER 13

# B Cells

Yong-Rui Zou • Christine Grimaldi • Betty Diamond

**KEY POINTS**

- **Immunoglobulins (Igs) are key to B cell function because they serve as both an antigen receptor and a major secreted product. The variable region binds antigen and is generated by random rearrangement of gene segments to give rise to numerous specificities. The constant region (Fc) defines the isotype and mediates effector functions.**
- **Surface Ig is the major component of the B cell receptor complex, which regulates B cell selection, survival, and activation. Secreted Ig mediates antigen neutralization and opsonization with uptake by phagocytic cells, complement activation, and cellular activation or inhibition through engagement of receptors for the Fc region of Ig.**
- **B cells are generated from hematopoietic precursors in the bone marrow and undergo several stages of maturation and selection before becoming immunocompetent, naïve B cells that reside in peripheral lymphoid organs. After antigen activation, B cells differentiate to memory cells and Ig-secreting plasma cells.**
- **Follicular B cells respond to protein antigens in a T cell–dependent fashion and are the major source of B cell memory. B1 and marginal zone B cells are less dependent on T cell help and display limited heterogeneity of the B cell receptor.**
- **Autoreactive B cells are generated in all individuals. Multiple checkpoints extinguish autoreactive B cells during early and later stages of B cell development. One or more of these checkpoints is breached in autoimmune-prone individuals, leading to the maturation and activation of autoreactive B cells.**

The immune system is composed of numerous cells that are required to generate innate and adaptive immune responses. Adaptive responses are characterized by immunologic memory generated during the first exposure to an antigen, thereby permitting a rapid response to the antigen after subsequent exposure.

B cells are lymphocytes that recognize antigens through a molecule called the B cell receptor (BCR). The BCR is a surface immunoglobulin (Ig) molecule that recognizes the antigen and is associated with two additional proteins, which transduce the signal. Upon encountering its antigen, a B cell begins a process of activation that leads to antibody secretion and memory formation regulated by interplay with antigen-activated T cells, dendritic cells (DCs), soluble factors, and in some cases follicular dendritic cells (FDCs). Both T and B lymphocytes can differentiate from naïve to memory cells, but only B cells have the capacity to fine-tune their antigen receptor structure to increase its specificity and affinity, giving rise to more effective antibodies. Beyond immunoglobulin secretion, B cells regulate the immune response by cytokine secretion and antigen presentation to T cells in the context of class II major histocompatibility complex (MHC) molecules.

Importantly, much of the knowledge of B cell biology has been generated in mouse models. However, in this chapter, human B cell biology is described whenever possible.

## IMMUNOGLOBULINS: STRUCTURE AND FUNCTION

The hallmark of a B cell is the expression of the Ig molecules. There are two forms of Igs, membrane-bound Igs and secreted Igs, that are generated through alternative messenger RNA (mRNA) splicing. Cell surface Ig, also termed BCR, contributes to B cell maturation and survival and initiates an activation cascade after contact with antigen. Secreted Igs, referred to as *antibodies*, are produced by B cells after antigen activation to protect the host through neutralization of the eliciting antigen.

Structurally, Igs are composed of four polypeptide chains: two identical light (L) chains with a molecular weight of approximately 25 kDa and two identical heavy (H) chains of 50 to 65 kDa. Each of the chains contains a folding motif that is highly conserved among proteins of the immune system, the "Ig domain." These domains constitute the backbone of the Ig molecule and help permit pairing of the polypeptide chains (Figure 13-1). The quaternary structure of an Ig molecule assumes a Y-shaped conformation that contains two functional moieties: two identical antigen-binding regions or variable regions, which are the arms of the "Y," and a constant region, which is the base of the "Y."[1]

This definition of functional moieties derives from early studies analyzing proteolytic fragments of Ig molecules. Cleavage with papain generates two identical fragments that retain antigen-binding capacity and hence are named Fab, as well as a distinct crystallizable fragment (Fc) that mediates immune effector functions but is unable to interact with antigen.[2]

The antigen-binding regions are formed by pairing of the variable domain of the L chain ($V_L$) to the variable domain of the H chain ($V_H$). In contrast to the remainder of the molecule, great diversity exists in the amino acid sequence

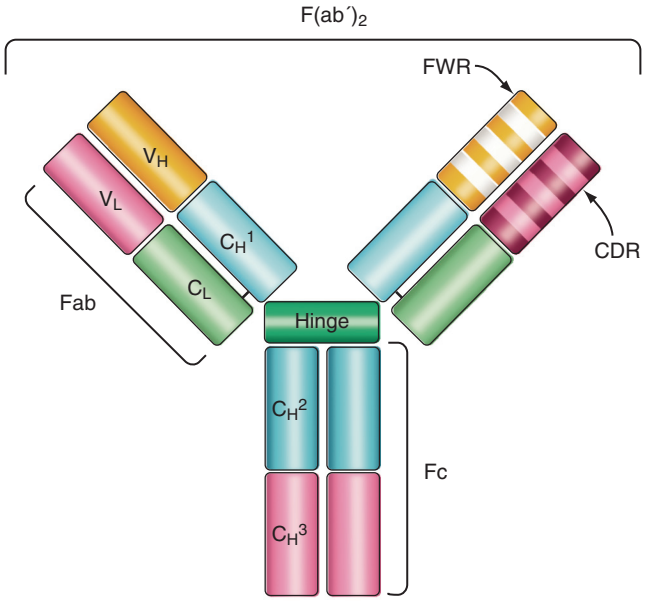

**Figure 13-1** Schematic of the antibody molecule. An antibody monomer consists of two heavy (H)-chain molecules covalently linked to two light (L)-chain molecules. The variable region is composed of the $V_H$ and $V_L$ domains of the H and L chains, respectively. Within the $V_H$ and $V_L$ domains are four framework regions (FWRs) and three complementary-determining regions (CDRs), which together make up the antigen-binding pocket. Papain digestion generates the Fab portion, which consists of $V_H$, $C_H1$, $V_L$, and $C_L$ domains, and pepsin digestion generates two covalently linked Fabs, known as the F(ab′)$_2$. The Fc region of the H-chain constant region, which mediates immune effector functions, consists of the hinge domain (only in immunoglobulin [Ig]G, IgA, and IgD), which increases flexibility and $C_H2$ and $C_H3$ domains.

of the variable domains, which allows for a broad repertoire of Ig molecules that can recognize a wide array of antigens. Within the variable region of the Ig molecule are discrete regions, known as *complementary determining regions* (CDRs) that make direct contact with antigen. The amino acid sequences of the CDR are highly variable and are flanked by more conserved amino acid sequences called *framework regions*. The H- and L-chain molecules each contain three CDRs and four framework regions (see Figure 13-1). The minimal antigenic determinant recognized by the variable regions of the H and L chains is known as an epitope, which may be a continuous or discontinuous region on a protein, carbohydrate, lipid, or nucleic acid. The presence of two identical variable regions in a single Ig molecule confers the capacity to interact with repetitive antigenic determinants present in multivalent antigens (i.e., polysaccharides) or enhances avidity by binding two separate antigen molecules containing the same antigenic determinant.[1]

The constant region directs the Ig effector functions that mediate the killing and removal of invading organisms and both the activation and homeostasis of the immune system. Strictly speaking, the constant region is formed by the constant domain of the L chain ($C_L$), which is paired to the first constant domain of the heavy chain ($C_H1$), and the remaining constant domains of the two heavy chains ($C_H2$ and $C_H3$ and $C_H4$ in IgM), paired to each other. However, the functions associated with the constant region are mediated by the constant domains of the H chain.

## Immunoglobulin Heavy Chain Constant Region

The specific binding interactions that occur between the Ig variable region and antigen may be sufficient to block microbial infectivity or neutralize toxins. However, the ability to eliminate pathogens is mediated by the Fc portion of the molecule. The Fc regions of antigen-antibody complexes are made accessible to serum factors that constitute the complement cascade or to cytotoxic and phagocytic cells that mediate the destruction and removal of pathogens. In mice and humans, there are five different types of H-chain constant regions, or isotypes, designated IgM (μ), IgD (δ), IgG (γ), IgA (α), and IgE (ε)[3]; each is encoded by a distinct constant region gene segment present in the H-chain locus of chromosome 4 in humans or chromosome 12 in mice. Each isotype is capable of specific effector functions, and each cellular receptor for Ig binds specific isotypes and initiates a distinct intra-cellular signaling cascade. The number of $C_H$ domains, the presence of a hinge region to increase flexibility between Fab regions, the serum half-life, the ability to form polymers, complement activation, and Fc receptor binding vary among isotypes. Characteristics of the different Ig H-chain isotypes are presented in Table 13-1.[1,3,4] BCRs of different isotypes may also deliver different intra-cellular signals when activated by antigen. It should be noted that the interplay between antibodies and the cells that bear the Fc receptors extends beyond pathogen clearance and shapes the immune response by mediating activation or inhibition of specific cell types[5] and by mediating cell death.[6]

### Immunoglobulin M

IgM is the first isotype expressed in developing B cells and the first antibody secreted during a primary immune response. It is found predominantly in serum but is also present in mucosal secretions and breast milk. Because the process that increases antibody affinity for a particular antigen (affinity maturation) has not yet been initiated during the early stages of a primary immune response, IgM antibodies usually exhibit low affinity. Their low affinity is balanced by the fact that much of the secreted IgM that exists is in pentameric form, generating multiple binding sites, providing high avidity for antigen, and assisting with the binding of large, multimeric antigens. IgM also exists as a monomer and a hexamer, but only the pentameric form is linked by the polypeptide, called the *joining* (J) chain. The J chain allows the active transport of IgM to mucosal secretions.[7]

Many of the biologic functions of IgM are mediated by its ability to activate the classic complement pathway.[1] The complement cascade consists of a series of enzymes that, upon activation, mediate the removal and lysis of invading organisms. Deposition of antibody molecules or complement components on the surface of the antigen assists with phagocytosis. Proteins such as antibody and complement that enhance phagocytosis are called *opsonins*. Once the complement cascade has been activated, monocytes, macrophages, or neutrophils engulf opsonized particles through specific receptors present on phagocytic cells such as CD21, which recognizes fragments of the C3 complement component. Activation of the complement pathway also results in

**TABLE 13-1** Properties of Human Immunoglobulin Isotypes

| Characteristic | IgM | IgG | IgA | IgE | IgD |
|---|---|---|---|---|---|
| Structure | Pentamer, hexamer | Monomer | Dimer ($IgA_2$), monomer ($IgA_1$) | Monomer | Monomer |
| $C_H$ domains | 4 | 3 | 3 | 4 | 3 |
| Serum values (mg/mL) | 0.7-1.7 | 9.5-12.5 | 1.5-2.6 | 0.0003 | 0.04 |
| Serum half-life (days) | 5-10 | 7-24 | 11-14 | 1-5 | 2-8 |
| Complement activation (classic) | Yes | Yes | No | No | No |
| FcR-mediated phagocytosis | No | Yes | Yes | No | No |
| Antibody-dependent cell mediated cytotoxicity | No | Yes | No | No | No |
| Placental transfer | No | Yes | No | No | No |
| Presence in mucosal secretions | Yes | No | Yes | No | No |
| Main biologic characteristic | Primary antibody response | Secondary antibody responses | Secreted immunoglobulin | Allergy and parasite reactivity | Marker for naïve B cells |

$C_H$, Constant domain of the heavy chain; FcR, Fc receptor; Ig, immunoglobulin.

the generation of the membrane attack complex, which is composed of late complement components and directly lyses C3-opsonized pathogens. Because activation of the classic complement pathway requires exposed Fc regions to be spatially close, multimeric IgM is a potent activator of the classic complement pathway once it has bound its antigen. For example, hexameric IgM is between 20 and 100 times more potent as an inducer of complement activation than is monomeric IgM.[8] C1q is an early complement factor that binds to IgM, as well as IgG. Immune complexes containing C1q can downregulate immune responses because C1q binds LAIR-1, a negative regulator that is present on the cell surface of myeloid cells and lymphocytes. LAIR-1, when associated with C1q, can suppresses inflammation by preventing DC maturation and activation induced by toll-like receptors (TLRs).

### Immunoglobulin G

IgG is the most common isotype found in serum, constituting about 70% of the circulating antibody. IgG antibodies are usually of higher affinity than IgM antibodies and predominate in a recall immune response. Four subclasses of IgG exist in humans: IgG1, IgG2, IgG3, and IgG4. IgG1 and IgG3 arise in response to viral and protein antigens. IgG2 is the main antibody present in response to polysaccharide antigens, and IgG4 participates in responses to nematodes and is observed in patients with IgG4-related systemic disease.[9]

All IgG subclasses exist as monomers and have a high structural similarity; however, minor differences result in distinct biologic effects. IgG3 and IgG1 are potent activators of the classic complement pathway, and IgG2 can initiate the alternative complement pathway (see Chapter 23).

All IgG subclasses engage specific Fcγ receptors (FcγRs) present on DCs, macrophages, neutrophils, and natural killer (NK) cells. The FcγRs on phagocytic cells, when cross-linked, mediate the removal of immune complexes from circulation and initiate antibody-dependent, cell-mediated cytotoxicity, resulting in the release of granules that contain perforin, a pore-forming protein, and enzymes known as *granzymes* that induce programmed cell death (apoptosis) of target cells.[10,11] FcγR engagement also allows the internalization and subsequent presentation of antigens in the context of class II MHC molecules.

Because IgG antibodies are the only ones that cross the placental barrier, they are critical for the survival of newborns. The transport of IgG from the maternal circulation into the fetal blood supply is mediated by the neonatal FcR (FcRn).[12] FcRn is also responsible for the long half-life of IgG in serum by blocking IgG catabolism.[13] FcRIIb is an important inhibitory receptor expressed on myeloid cells and B cells. Its function is discussed in more detail in the later Surface Co-Receptors section.

### Immunoglobulin A

Despite its relative low concentration in serum, more IgA is produced than all other isotypes combined. Most IgA exists as secretory IgA (SIgA) in mucosal cavities and in milk and colostrum, and only a small fraction is present in serum. Two subclasses of IgA exist in humans: IgA1 and IgA2. IgA1 is mainly produced as a monomer. In contrast, polymeric IgA2 is produced along mucosal surfaces.[14]

Polymeric IgA exists mainly as a dimer and includes a J chain (the same chain that links pentameric IgM). It is captured by the polymeric immunoglobulin receptor (pIgR) that is expressed on the basolateral surface of the epithelial cells and then transcytosed to the apical side. Release of IgA into mucosal secretions requires cleavage of the pIgR; a fragment known as the secretory component (SC) remains associated with SIgA and protects it from the action of proteases and increases its solubility in mucus, where it neutralizes toxins and inhibits the adherence of SIgA-coated micro-organisms to the mucosal surface.[15]

People with IgA deficiency have reduced levels of both serum and secreted IgA and are prone to respiratory tract and diarrheal infections, as well as an increased incidence of autoimmune disorders.[16] The presence of FcαR on the surface of neutrophils and macrophages has been suggested

to play a regulatory role in the immune system; it is possible that autoimmune manifestations in IgA-deficient patients arise from the absence of immune regulation mediated by FcαR.[17]

### Immunoglobulin E

IgE is involved in protection against parasitic infections but also triggers immune responses associated with allergic reactions. Only a small amount of IgE is detectable in serum, where it exists as a monomer.[18] Mast cells and basophils express a high-affinity IgE Fc receptor (FcεRI) that binds free IgE. Cross-linking of the FcεR by antigen binding to the IgE induces degranulation and release of histamine, proteases, lipid mediators such as prostaglandin $D_2$, and leukotrienes, many of which are associated with anaphylaxis.

### Immunoglobulin D

The role of IgD in the humoral response has been the subject of multiple speculations. IgD is found predominantly as a membrane-associated Ig on mature naïve B cells. Soluble IgD is scarce in serum; however, IgD-producing plasma cells are found in tonsils and tissue associated with the respiratory tract. High levels of secreted IgD can be found in persons with immunodeficiencies.[19]

## Light Chains

Two distinct L-chain polypeptides exist, designated κ and λ. L chains contain a variable and a single constant domain. Even though two L-chain isotypes exist, there is no known function associated with the L-chain constant region. The κ chain is used more often than the λ chain in human (65%) and mouse (95%) Ig molecules.[20]

## Immunoglobulin Variable Region

The recognition of a virtually unlimited number of antigens requires a mechanism to generate Ig molecules with similarly broad specificities. The molecular basis of this process has been known for several years.[21] The Ig molecule is encoded by gene segments within distinct genetic loci residing on separate chromosomes (Figure 13-2); the H-chain locus is on human chromosome 14,[22] the κ-chain locus is on chromosome 2, and the λ-chain locus is on chromosome 22.[23]

The H-chain variable region is encoded by a variable ($V_H$), diversity ($D_H$), and a joining ($J_H$) segment. The L chain is encoded by either $V_κ$ and $J_κ$ or $V_λ$ and $J_λ$ segments; it does not contain D segments. The human H-chain locus contains from 38 to 46 $V_H$, 23 $D_H$, and 9 $J_H$ functional genes (these numbers represent a typical haplotype but vary among individuals). The κ-chain locus contains approximately 31 to 35 $V_κ$ genes and 5 $J_κ$ functional genes; the λ-chain locus contains 29 to 32 $V_λ$ genes and 4 or 5 $J_λ$ functional genes.[24]

### Generation of Immunoglobulin Diversity

In a developing B cell, different $V_H$, $D_H$, and $J_H$ or $V_L$ and $J_L$ gene segments are randomly combined to generate a large number of different Ig molecules (Figure 13-2). This process,

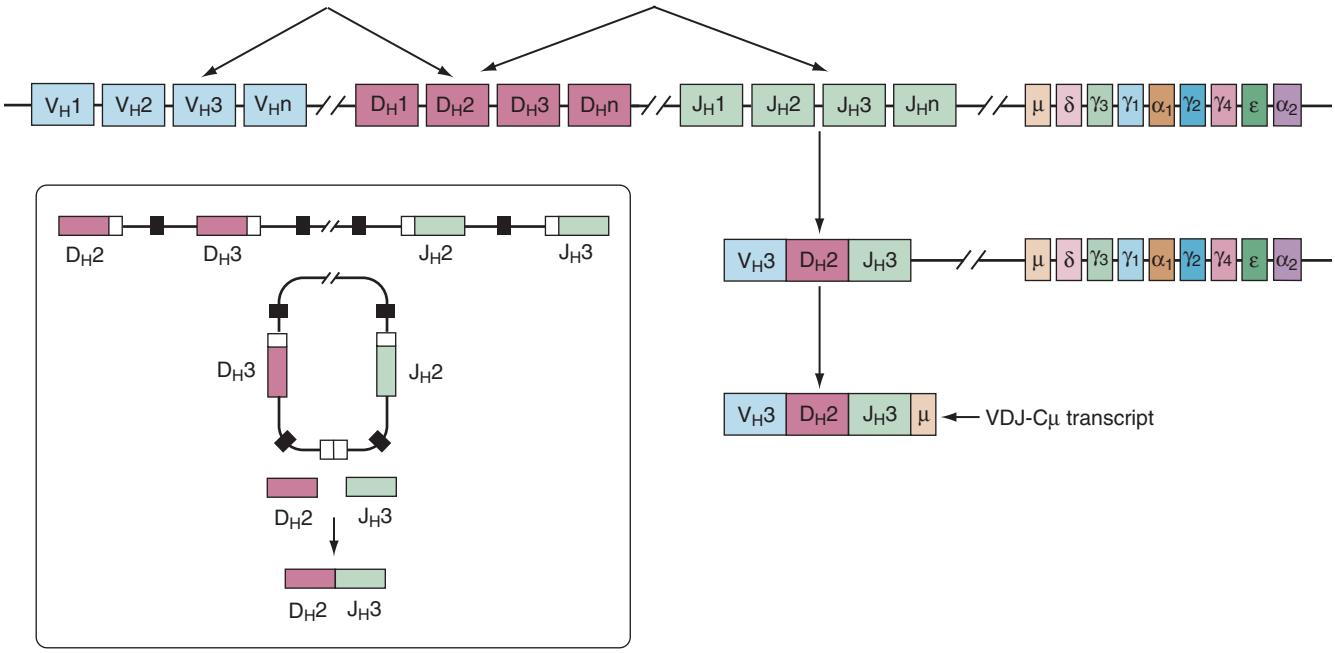

**Figure 13-2** V(D)J recombination at the immunoglobulin gene locus. V(D)J recombination at the heavy (H)-chain locus is depicted at the top. A single $V_H$ gene segment randomly recombines with a $D_H$ and $J_H$ gene segment residing on the same chromosome. After $V_HD_HJ_H$ recombination, a transcript containing the immunoglobulin (Ig)M H-chain constant region gene (Cμ) is generated. The *inset* represents an example of V(D)J recombination occurring between a single $D_H$ and $J_H$ gene segment. The *white squares* represent the heptamer, and the *black squares* represent the nonamer recombination recognition sequences. After recognition and cleavage of these sequences, the coding junctions of the rearranged $D_H$ and $J_H$ gene segments are ligated. A $V_H$ gene segment then recombines with the rearranged $D_HJ_H$ segment. Light (L)-chain rearrangement is mediated by the same mechanism.

known as V(D)J recombination, occurs in the fetal liver or adult bone marrow, in the absence of antigen stimulation, and must be successful to continue with B cell maturation. Here, we present the molecular process, and later the functional and developmental consequences are discussed (see the B Cell Development section).

V(D)J recombination happens sequentially, beginning with the joining of one $D_H$ segment to one $J_H$ segment; then a $V_H$ segment will be targeted to the rearranged $D_HJ_H$ fragment. The absence of an in-frame recombination leads to recombination of the second allele. L-chain recombination also occurs in a stepwise manner. First, the κ locus is rearranged; in the absence of a productive κ-chain rearrangement, the λ locus undergoes recombination.[25]

The recombination machinery is composed of specific enzymes, including recombination-activating gene 1 and 2 (RAG-1 and RAG-2). The complex recognizes recombination signal sequences (RSS) that flank the V, D, and J gene segments. These highly conserved sequences are composed of a palindromic heptamer (7 base pairs) followed by DNA spacers that are 12 or 23 base pairs in length and an adenosine/thymidine (AT)-rich nonamer.[26] Once the complex recognizes its target, it generates double-stranded DNA (dsDNA) breaks at the RSS sites. Next, the cellular DNA repair complex recognizes and joins the cleaved segments.

The random recombination that occurs among V, D, and J gene segments can generate a diverse Ig repertoire without the need for a large number of germline H- and L-chain genes. During H-chain recombination, nucleotides may be added at $V_HD_H$ and $D_HJ_H$ junctions by the enzyme terminal deoxynucleotidyl transferase (TdT). These non–germline-encoded sequences are known as *N additions*. As long as these nucleotide changes do not disrupt the reading frame or lead to the incorporation of premature stop codons, the random addition of N sequences increases the diversity of the amino acid sequence. Imprecise ligation at the coding junctions may result in the loss of nucleotides, thereby also enhancing diversity. Finally, random pairing of the H chains and L chains further diversifies the Ig repertoire.

## B CELL DEVELOPMENT

The final outcome of the maturation process is the generation of a pool of mature B cells with a diverse repertoire of Ig specificities that can recognize foreign and pathogenic antigens without compromising the integrity of the self. Therefore the process of generation of Ig diversity is coupled with the censoring of autospecificities.

B cells, as with all cells in the hematopoietic lineage, begin with the differentiation of noncommitted $CD34^+$ hematopoietic stem cells to lymphopoietic precursors with restricted lineage potential. These cells, known as *common lymphoid progenitors* (CLPs), have the potential to give rise to NK, T, and B cells. Early B cell progenitors begin to express genes for DNA rearrangement, as well as B cell program transcription factors. Multiple transcription factors act in concert, but Ikaros, E2A, EBF, and Pax5 appear to be the most important in B cell development.[27] Pax5 is considered the master transcriptional control for B cells because it is induced in early stages of B cell commitment and plays a dual role by repressing genes required for differentiation to the myelomonocytic lineage and activating B cell–specific genes such as Ig genes, CD19, and signaling molecules.[28]

### Niches for Human B Lymphopoiesis

The development of hematopoietic stem cells ($CD34^+$) into mature B cells begins in the first weeks of uterine life. By the eighth gestational week, early B cell precursors can be identified in the fetal liver and omentum. From gestational week 34 and through adulthood, the bone marrow is the primary site of B lymphopoiesis.[29] It has been unequivocally established that there are differences between the B cells that originate during fetal and adult lymphopoiesis in mice, and it is becoming clear that these differences extrapolate to human lymphopoiesis as well. B cell precursors are susceptible to estrogen, and the maturation of maternal B cells is arrested at the pro–B cell stage during pregnancy; in contrast, fetal B cell precursors lack estrogen receptors and consequently are unaffected by exposure to hormones.[30] B cells originating during prenatal life have a bias in the usage of $D_H$ and $J_H$ gene segments, and this, along with low expression of the enzyme TdT, leads to a more restricted Ig repertoire with shorter CDR3.[31]

Whether during fetal or adult lymphopoiesis, the maturation of B cells from multipotential progenitors is contingent on the presence of stromal cells that provide both contact-dependent and soluble signals. Although the nature of the interactions provided by the stromal cells to create a lymphopoiesis-permissive environment is still largely unknown, they include both survival and proliferative signals. Stromal-derived factor 1 (SDF-1) is required for homing of the early B cell precursors to sites of lymphopoiesis.[32] Interactions between vascular cell adhesion molecule-1 (VCAM-1) on the membrane of the stromal cells and its ligand, very late activation antigen-4 (VLA-4), on early B cell progenitors are required for B cell differentiation. The molecules interleukin (IL)-7, IL-3, and the Fms-like tyrosine kinase-3 (Flt-3) ligand promote B cell lymphopoiesis, although IL-7 appears to be dispensable for human B cell development. Matrix molecules in the microenvironment such as heparan sulfate proteoglycan are assumed to "trap" critical soluble factors.[33]

### B Cell Ontogeny

The stages of B cell development are defined by the state of Ig gene rearrangement and the expression of intra-cellular and surface proteins. The nomenclature and classification of particular stages vary slightly among different laboratories working in this field. For simplicity, we have divided the stages of B cell lymphopoiesis into early B cell progenitors, pro-B, pre-B, immature, transitional, and mature naïve B cell (Table 13-2). When a CLP begins to transcribe mRNA coding for the proteins required for B cell maturation, E2A and EBF, the cell becomes an early B cell progenitor. Once these two transcription factors are expressed, they enable transcription of the proteins involved in the recombination machinery (RAG-1/RAG-2). The beginning of D to J recombination on the IgH locus marks the progress to a pro-B stage.

**TABLE 13-2** Human B Cell Maturation Markers during B Cell Development

| Marker | HSC | Pro-B | Pre-B | Immature | Transitional 1 | Transitional 2 | Plasma |
|---|---|---|---|---|---|---|---|
| CD34 | + | + | – | – | – | – | – |
| CD19 | – | + | + | + | + | + | + |
| CD10 | – | + | + | + | + | + | – |
| CD20 | – | + | + | + | + | + | – |
| CD21 | – | – | – | – | – | + | – |
| CD22 | – | – | + | + | + | + | – |
| CD23 | – | – | – | – | – | + | – |
| CD38 | – | + | + | + | + | + | + |
| CD40 | – | + | + | + | + | + | – |
| CD45 | – | + | + | + | + | + | + |
| CD138 | – | – | – | – | – | – | + |
| RAG-1 | – | + | + | +/– | +/– | +/– | – |
| RAG-2 | – | + | + | +/– | +/– | +/– | – |
| TdT | – | + | + | – | – | – | – |
| Igα | – | + | + | + | + | + | + |
| Igβ | – | + | + | + | + | + | + |
| Heavy chain | – | – ($D_H$–$J_H$) | + ($V_H$–$D_H$-$J_H$) | + | + | + | + |
| Pre-BCR | – | – | + | – | – | – | – |
| Surface IgM | – | – | – | + | + | + | – |
| Surface IgD | – | – | – | – | – | + | – |
| Light chain | – | – | + ($V_κ$-$J_κ$ $V_λ$-$J_λ$) | + | + | + | + |

BCR, B cell receptor; CD, cluster of differentiation; HSC, hematopoietic stem cell; Ig, immunoglobulin; RAG, recombination-activating gene; Tdt, terminal deoxynucleotidyl transferase.

## Pro-B Cells

The pro-B cell stage is defined by the rearrangement of the IgH chain gene segments and synthesis of a μ-polypeptide. Pro-B cells are dependent on interactions with endothelial cells present in the stroma. The VLA-4 integrin and CD44 both mediate adhesion to stromal cells, are highly expressed at this stage, and are believed to be important for continued development.[34] Pro-B cells also express high levels of B cell lymphoma 2 (Bcl-2), a molecule that protects cells from apoptosis. At the onset of the pro-B cell stage, the variable gene segments of both H- and L-chain loci are in the unrearranged germline configuration but accessible to the recombination machinery. A $D_H$ gene segment on one H-chain chromosome rearranges with a $J_H$ gene segment residing on the same chromosome, often with the inclusion of nontemplate nucleotides at the junction of these two segments. Next, a $V_H$ gene rearranges to the $D_HJ_H$ gene fragment. Completion of $V_HD_HJ_H$ gene rearrangement leads to the generation of an H-chain transcript that also contains the IgM constant region ($C_μ$), which is the constant region gene most proximal to the variable region genes on the chromosome (see Figure 13-2).

The generation of a μ-polypeptide and its subsequent expression on the surface of the cell, together with a surrogate L chain formed by the λ5 and Vpre-B polypeptides, as well as the Igα/Igβ dimer—a complex known as the pre-B cell receptor (pre-BCR)—marks the end of this phase of gene recombination. This constitutes a critical developmental checkpoint and the entrance to the next developmental stage, known as the *pre-B cell*.[35] The requirement for a pre-BCR complex ensures that B cells without a productive H chain will not undergo further differentiation.

The pre-BCR stimulates pro-B cells with productive IgH rearrangement to proliferate. It also transduces a signal that the V(D)J rearrangement was successful and halts recombination of the second H-chain allele. This process, known as *allelic exclusion*, ensures that all Ig molecules generated within a single B cell are identical and have the same antigenic specificity. If no μ chain is generated, rearrangement is initiated on the other chromosome. If the second rearrangement also results in a nonproductive H-chain molecule, the absence of a pre-BCR–mediated signal induces apoptosis. The odds of generating a productive rearrangement are one in three, and consequently, approximately 50% of the cells that begin recombination will be unable to proceed along a developmental pathway.

## Pre-B Cells

The pre-B cell stage is characterized by L chain recombination. Initiation of this stage requires the presence of the pre-BCR and functional signal transduction machinery.

At the transitional stage from pro-B to pre-B cells, the expression of the pre-BCR induces a proliferative burst that generates daughter cells with the same H chain and

potential for multiple specificities within daughter cells, each of which may produce a different L chain. Targeted disruption of genes encoding the pre-BCR complex such as the IgM transmembrane constant region domain, λ5, or the Igα and Igβ accessory molecules results in a profound decrease in developing B cells. In addition, defects in the adapter molecule BLNK or the tyrosine kinase Btk lead to a serious impairment in pre-B cell maturation. It appears that the charged residues on pre-BCR induce self-aggregation, which activates constitutive internalization and signaling of the pre-BCR complex that leads to clonal expansion of B cell precursors with a fit pre-BCR.[36]

The expression of the pre-BCR is transient. After the proliferative burst, the μ H chain is present only in the cytoplasm as the pre-B cell rearranges an L chain. The general rearrangement process is similar to V(D)J rearrangement and is dependent on RAG-1/RAG-2 expression. Because TdT is not expressed in this stage, L chains do not usually contain N sequences at the $V_LJ_L$ junction. At the end of this process, pairing of the newly minted L chain with the μ H chain leads to the surface expression of an IgM molecule, complexed with Igα and Igβ, to form the BCR complex. It is believed that surface expression of the BCR on immature B cells transduces signals that enforce allelic exclusion at the L-chain locus and downregulate expression of the RAG genes. This immature B cell has completed the gene rearrangement process and is now subject to repertoire selection.[37]

### Immature B Cells

Once B cells express surface IgM in the bone marrow, they are subject to *repertoire censoring*. During this stage, cross-linking of the BCR by antigen leads to the activation of one of several tolerance mechanisms. These mechanisms include deletion, receptor editing, and anergy and diminish the fraction of autoreactive cells present in the mature repertoire (see later discussion on negative selection).

During the maturation process in the bone marrow, the cells become less dependent on interactions with the stroma and move toward the sinusoidal lumen. Once they express IgM, they begin to move into blood, where they are called *transitional cells*.

## Peripheral Naïve B Cell Subsets

As B cells mature and their dependence on stromal cells decreases, they leave the bone marrow and finish their maturation in the spleen before homing to other lymphoid tissue such as the lymph nodes, tonsils, and Peyer's patches of the intestine. It is in these secondary lymphoid organs where mature B cells interact with foreign antigen and specific humoral immune responses are activated.

### Transitional B Cells

Once immature B cells egress from the bone marrow, they are called *transitional cells*. These cells are the earliest B cells found in the periphery in healthy subjects and move to the spleen to finish their maturation.

Transitional cells are the last B cell subpopulation that expresses the developmental marker CD24. At this stage B cells begin to express surface IgD, which harbors the same specificity as the IgM because the IgD H chain is encoded by the same VDJ fragments as IgM but expresses the $C_\delta$ instead of the $C_\mu$ domain. It is the expression of IgD that separates transitional cells into two different maturation stages. Transitional 1 (T1) B cells that do not express IgD are the recent bone marrow emigrants, and transitional 2 (T2) B cells that begin to express IgD represent the subsequent maturational stage.[38] The existence and functional characteristics of a third transitional stage (T3) are still debated.

Transitional cells constitute a stage subject to multiple regulatory processes. First, transitional cells must compete with naïve B cells already present in the periphery for a developmental niche. Transitional B cells are extremely dependent on a B cell survival factor known as *B cell–activating factor of the tumor necrosis factor family* (BAFF or BLyS). In its absence, B cell development does not progress beyond the T1 stage.[39] Second, T1 transitional cells are still highly susceptible to tolerance induction after BCR cross-linking. In T1 cells, cross-linking of the BCR ex vivo has been shown to lead to cell death, whereas T2 cells respond to BCR cross-linking by proliferation and differentiation to the mature naïve B cell stage.

### BAFF Family of Cytokines

The cytokine milieu surrounding the B cell is diverse and spatially and temporarily regulated. Although B cells are modulated by multiple cytokines, in recent years two members of the tumor necrosis factor (TNF) family, BAFF and APRIL, have emerged as key survival factors, particularly at two regulatory points in development and differentiation: the transition from an immature to a naïve B cell in the periphery and the survival of the newly produced plasma cells. BAFF (B cell–activating factor, BLyS) and APRIL (a proliferation-inducing ligand) are proteins produced by cells that take part in the innate response such as macrophages and DCs, as well as stromal cells, and are present as membrane-bound proteins or soluble trimers. They have three known receptors (BAFF-R, TACI, and BCMA) that are present on the membrane of B cells from the T2 stage to their final differentiation to plasma cells. BAFF binds the three receptors, whereas APRIL binds only TACI and BCMA. BAFF induces survival and activation of B cells when bound to BAFF-R, whereas BAFF signaling through TACI decreases the size of the B cell pool. APRIL does not participate in B cell homeostasis but seems to be critical to the survival of plasmablasts in the bone marrow.[40]

Enhanced survival and activation of autoreactive B cells have been demonstrated in mice that overexpress BAFF.[41] An increase in serum levels of BAFF has been observed in some patients with systemic lupus erythematosus (SLE), rheumatoid arthritis, and Sjögren's syndrome and is thought to contribute to pathogenesis because autoreactive B cells that would normally be censored can survive in the presence of excess BAFF[42] (Figure 13-3).

### Mature B Cells

The final stages of maturation that occur in the spleen and give rise to the naïve B cell subset have not been fully

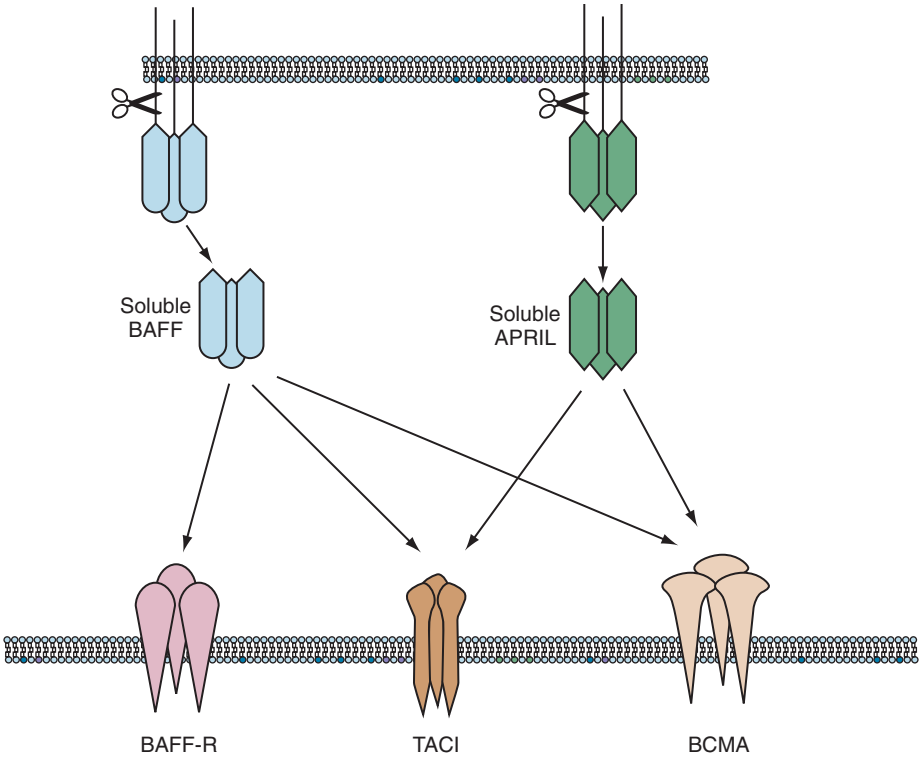

**Figure 13-3** The BAFF family of cytokines and their receptors. BAFF (also known as BLyS) and APRIL are expressed as membrane-bound proteins that can be cleaved by proteases to produce the soluble proteins. BAFF might bind the three known receptors: BAFF-R, TACI, and BCMA. APRIL only binds to BCMA and TACI.

elucidated, but the prevailing theory is that T2 B cells give rise to the circulating mature naïve cell population. In the mouse, two populations of phenotypically and functionally different naïve B cells are recognized: follicular and marginal zone (MZ) B cells. Human naïve B cells constitute 60% to 70% of the circulating B cell repertoire and populate the spleen and lymph nodes. They include the equivalent of mouse follicular B cells and represent the circulating, nonantigen-exposed B cell subpopulation characterized by surface IgM and IgD expression, lack of CD27, and the presence of the membrane transporter ABC.[43] There is also a population in blood of $IgM^+$, $CD27^+$ B cells that have been likened to MZ B cells, which do not recirculate in the mouse.[44]

### Marginal Zone B Cells

MZ B cells are a population of noncirculating mature B cells located in the MZ of the rodent spleen. In rodents, MZ B cells present clear phenotypic and functional differences to the cells present in the follicles, responding to blood-borne pathogens and to repetitive antigenic structures such as the ones present on polysaccharide antigens.

In the human spleen, the structural definition of the MZ does not correspond exactly to the area surrounding B cell follicles. However, there is a population with the functional characteristics of mouse MZ B cells: low activation thresholds, highly responsive to polysaccharide antigens and with a clear surface phenotype, can be differentiated. These cells, which are sometimes named *MZ-like* or *unswitched memory*, are not restricted to the human spleen but are found circulating in the peripheral blood, as well as in the lymph nodes, tonsils, and Peyer's patches.[44,45] They are defined as $IgM^{high}$, $IgD^{low}$, $CD27^+$, $CD21^+$, and $CD1c^+$.[45,46]

Given that these cells possess the "memory" marker CD27, it has been suggested that they have experienced antigenic exposure; however, the presence of MZ-like B cells in subjects with X-linked agammaglobulinemia (a CD40L deficiency) suggests that even if antigen exposure has occurred, T cell help has not.

Interestingly, MZ-like B cells, although already present at birth, do not seem to be fully functional at that time; infants up to age 2 years are particularly susceptible to infections by capsulated bacteria. This phenomenon might be due to the functional immaturity of the cells or to the lack of development of the antigen-trapping microstructure.

### B1 Cells

In mice, B1 cells represent a minor population of B cells that reside predominantly in the pleural and peritoneal cavities. They are named B1 because it is assumed that is the first population of B cells to develop during intrauterine life.

Functionally, B1 cells have been characterized as self-renewing cells that possess a limited BCR repertoire and respond with low affinity to a broad array of antigens, mainly phospholipids and carbohydrate structures in the bacterial cell wall. Despite their low numbers, these cells secrete most of the natural antibodies of the organism (antibodies that appear without evidence of previous immunization) and are assumed to be the precursors of most of the plasma cells that

home to the intestinal *lamina propria*. Phenotypically, these cells are defined as $IgM^{high}$ and $IgD^{low}$. About 70% of them express the marker CD5.

In humans, the definition of B1 cells is still unresolved. The CD5 marker has been used extensively as a surrogate marker for B1 cells with mixed success, given that activated human B cells also upregulate the expression of CD5.[47]

## SITES OF B CELL HOMING AND ACTIVATION

After the immature B cell stage, B cells home to secondary lymphoid organs, which contain the microenvironment and architecture necessary for the retention and activation of B cells. These organs include the spleen and lymph nodes, as well as lymphoid structures in mucosal tissue (e.g., Peyer's patches, appendix, and tonsils). The secondary lymphoid tissue is adapted to trap circulating antigen and expose the B cells to it and to provide interactions with T cells and other co-stimulatory cells. Peripheral lymphoid tissue contains specialized antigen-presenting cells known as *dendritic cells*. In the Peyer's patches of the intestines, foreign antigen is taken up in specialized epithelial cells known as *M cells*. Even though peripheral lymphoid tissues vary in structure and cellular organization, they all possess antigen-presenting cells and B cell–containing follicles surrounded by T cell–rich zones.[48] As explained in the following section, antigen, T cells, and DCs are required for B cell activation and differentiation into Ig-secreting plasma cells or memory B cells.

### Circulation and Homing

B1 cells typically home to the peritoneal and pleural cavities and, to a lesser extent, the spleen. Naïve B cells enter the peripheral circulation by passing through the endothelial lining of the sinusoids of secondary lymphoid tissue and recirculate throughout the follicles of secondary lymphoid tissues. The entry, retention, and recirculation of B cells through secondary lymphoid organs depend on both adhesion molecules and chemokine receptors.[49,50] First, expression of LFA-1 and VLA-4 is required for entry into the lymphoid tissue, and then the chemokine receptors CXCR5 and CCR7 direct localization within the tissue. The CXCR5 molecule is expressed on all mature B cells and mediates B cell migration to follicles in response to the chemokine CXCL13, which is produced by follicular stromal cells. These cells, in turn, are regulated by lymphotoxin made by B cells. In the follicle, the B cells scan for antigen, making contact with potential antigen-bearing cells such as FDCs, subcapsular macrophages, and DCs. If the B cell does not encounter a cognate antigen, it will exit the lymphoid organ through the efferent lymphatics in response to the molecule sphingosine 1 phosphate (S1P). Neutralization of S1P leads to sequestration of B cells in lymphoid organs.[51]

Upon antigenic encounter, the B cells are retained in the lymphoid organ because of the upregulation of CCR7. The ligands for CCR7 (CCL19 and CCL21) mediate the organization of the T cell zone and attract antigen-activated B cells to this area, where cognate T cell–B cell interactions occur.

In contrast, it is assumed that MZ-like B cells respond to antigen without the help of cognate T cells. In mice, MZ B cells are present exclusively in the spleen and do not recirculate; in humans they are found in the spleen and tonsils, as well as in blood. MZ B cells localize to the outer layers of the follicles, making them among the first cells to encounter blood-borne antigens. The adhesion molecules ICAM-1 and VCAM-1, as well as S1P and cannabinoid receptor 2, are responsible for sequestering MZ B cells within the marginal sinuses.

The interplay of chemokine expression and the induction of chemokine receptors play an important role in the germinal center (GC) response. The chemokine CXCL12 retains centroblasts in the dark zone during the process of somatic hypermutation and isotype class switching. CXCL13 regulates migration to the light zone, where survival and selection events are mediated by interactions with CXCR5-expressing T follicular helper (Tfh) cells and FDCs.[52] Later, CXCL12 promotes the migration of plasmablasts to the bone marrow, where they undergo further development into long-lived plasma cells.

### Mucosa-Associated Compartments

Within the mucosal tissue, the sites of induction of immune responses are distinct from the site where the effector cells reside. There are two main sites for the induction of an immune response. The first is the mucosa-associated lymphoid tissue (MALT) that includes Peyer's patches, nasopharynx-associated tissue, and isolated lymphoid follicles, where exogenous antigen is displayed by specialized M cells that transport antigen to the follicle. The second site of induction includes mucosa-draining lymphoid nodes such as the mesenteric and cervical lymph nodes.[52]

B cells reach these sites through the systemic circulation. Once they are stimulated by antigen and induced to differentiate, they home to the effector sites in the intestinal and respiratory lamina propria, where they differentiate into plasma cells and produce antibody mainly of the IgA isotype. An interesting characteristic of the plasma cells induced in the mucosal compartments is their selective homing to mucosal effector sites. Nasal activation leads to IgA-secreting cells with high levels of CCR10 and $\alpha4\beta1$ integrins that home to the respiratory and genitourinary tracts in response to their ligands, CCL28 and VCAM-1. Migration to the intestinal lamina propria, in contrast, seems to be dependent on orally induced activation and subsequent expression on B cells of the chemokine receptor CCR9 and integrins that bind to CCL25 and MADCAM1/VCAM-1, respectively.[53]

## B CELL ACTIVATION AND DIFFERENTIATION

Engagement of surface Ig by antigen triggers a series of cellular events that regulate B cell proliferation and differentiation. Receptor cross-linking leads to relocation of the BCR to microdomains known as *lipid rafts*, which leads to the rapid activation of proximal mediators of the BCR signal transduction pathway.[54] This results in the activation of second messengers such as phospholipase C, phosphatidylinositol 3-kinase (PI3K), and Ras pathways. Induction of these pathways ultimately transmits signals to the nucleus,

initiating new gene expression. Depending on the type of signal delivered and the stage of maturation of the B cell, B cells can undergo either differentiation into memory B cells and plasma cells, or apoptosis. Along with surface Ig, several other membrane receptors modulate antigen-induced signal transduction.

## B Cell Receptor Signaling

B cell activation is triggered by the binding of specific antigen to the BCR. The end result of this process will depend on the characteristics of the antigen, the B cell subpopulation activated, and the co-stimulatory signals provided by the antigen itself, T cells, and the microenvironment.

The BCR complex is composed of surface Ig, noncovalently bound to a dimer formed by the molecules Igα and Igβ. The surface Ig on the naïve B cell includes both IgM and IgD. The role of surface Ig is to recognize foreign antigen; the Igα and Igβ molecules transduce the signal through their cytoplasmic tails that contain a particular amino acid sequence known as an *immunoreceptor tyrosine-based activation motif* (ITAM). This sequence contains two tyrosine residues that can be phosphorylated upon activation. After phosphorylation, the ITAM acts as a docking site for the Src homology-2 (SH2) domain to recruit tyrosine kinases and other signaling molecules.

BCRs on resting B cells are highly mobile within the plasma membrane, and they generate a ligand-independent tonic signal that is essential for B cell survival.[55,56] After cross-linking by antigen, BCRs aggregate and translocate to cholesterol- and sphingolipid-enriched membrane microdomains named *lipid rafts*.[54] The signal transduction events that occur after BCR cross-linking are mediated by the subsequent recruitment and activation of intra-cellular kinases including Lyn, Fyn, Btk, and Syk. The most proximal event after BCR cross-linking is the activation of Lyn, which results in the activation of the phosphatase CD45. CD45 removes the inhibitory phosphates on the ITAMs of Igα and Igβ, and the activation of Lyn leads to the activation of Syk and Btk.[57] There is evidence that ligation of CD19, an activating co-receptor of the BCR, leads to recruitment and activation of Vav, PI3K, Fyn, Lyn, and Lck.[58] Subsequently, the tyrosine kinases Syk and Btk are activated by tyrosine phosphorylation. The phosphorylation of Syk triggers the activation of phospholipase C (PLC), PI3K, and Ras pathways. The activation of Syk appears to be absolutely critical for BCR-mediated signal transduction because Syk-deficient cell lines exhibit a loss of BCR-induced signaling. Btk also appears to be required for the activation of second messenger pathways. In some patients with X-linked agammaglobulinemia, a mutation in the *BTK* gene results in impaired BCR signaling at the pre-B cell stage.[57] As a consequence, these patients have a greatly reduced number of mature B cells and generate poor antibody responses. In mice, however, a mutation in *Btk* leads to a disease known as *X-linked immunodeficiency*. B cell development is impaired at the transitional T2 stage, and B cells that do go on to maturity are unable to respond to certain T cell–independent antigens.

After recruitment and activation of the intra-cellular kinases, downstream pathways are initiated. Btk, Syk, and the adapter molecule BLNK are required for the activation of phospholipase C gamma. This leads to breakdown of phosphatidylinositol 4-phosphate to DAG and inositol 1,4,5-triphosphate ($IP_3$) to trigger calcium release from intra-cellular stores and the subsequent translocation of nuclear factor of activated T cells (NFAT) to the nucleus. In addition, Btk activates Ras, which leads to nuclear translocation of the transcription factor activator protein-1 (AP-1). BCR cross-linking also activates mitogen-activated protein (MAP) kinases (Figure 13-4).

Induction of these pathways ultimately transmits signals to the nucleus, where signals are integrated to regulate gene expression. One of the main transcriptional activators related to B cell activation is nuclear factor (NF)-κB, a family of transcriptional factors consisting of homodimers or heterodimers of different subunits. NF-κB regulates cellular processes leading to activation, differentiation into memory B cells and plasma cells, and apoptosis.

## Surface Co-Receptors

Along with surface Ig, many molecules can modulate BCR signal transduction by either enhancing or diminishing the signal activated by antigen. These molecules include, but are not limited to, the B cell co-receptor complex (CD19/CD21/CD81/Leu-13), CD45, SHP1, SHP2, SH2 containing inositol 5-phosphatase (SHIP), CD22, FcγRIIB1, CD5, CD72, PIR-B, and PD-1 (see Figure 13-4). The integration of all these signals sets the threshold for activation of the BCR signal.

The main positive regulator of B cell activation is the B cell co-receptor complex, composed of CD19, CD21, CD81, and an interferon-inducible molecule called *Leu-13*.[59] After antigen cross-linking of surface Ig, specific tyrosine residues contained within the CD19 cytoplasmic domain rapidly become phosphorylated. Although the natural ligand for CD19 is not known, in vitro studies have demonstrated that ligation of CD19 with anti-CD19 antibody lowers the threshold required for BCR-mediated B cell activation and enhances the proliferative effect of anti-IgM treatment on B cells.[60] A role for CD19 in B cell activation has been clearly defined in mice that either lack or overexpress CD19.[61] The CD19 molecule is required for T cell–independent and T cell–dependent B cell responses and for GC formation. The CD21 molecule serves as a receptor for cleavage fragments of the C3 component of complement. Cross-linking of the BCR and CD21 with complement-coated antigen has been proposed to trigger the activation of the cytoplasmic tail of CD19. Mice deficient in CD21 also have impaired responses to T cell–dependent and T cell–independent antigens and a defect in GC formation.[62] The functions of the remaining two components of the B cell co-receptor complex, CD81 and Leu-13, have not been characterized, although it has been suggested that these molecules may mediate homotypic cell adhesion.

In contrast, CD22 that also associates with the BCR is primarily a negative regulator of BCR activation. Although CD22 contains an ITAM motif and is able to recruit Src tyrosine kinases to its cytoplasmic domain,[63] it also contains a specific motif known as the *immunoreceptor tyrosine-based inhibition motif* (ITIM). Similar to the ITAM, the ITIM contains a critical tyrosine residue. After activation of

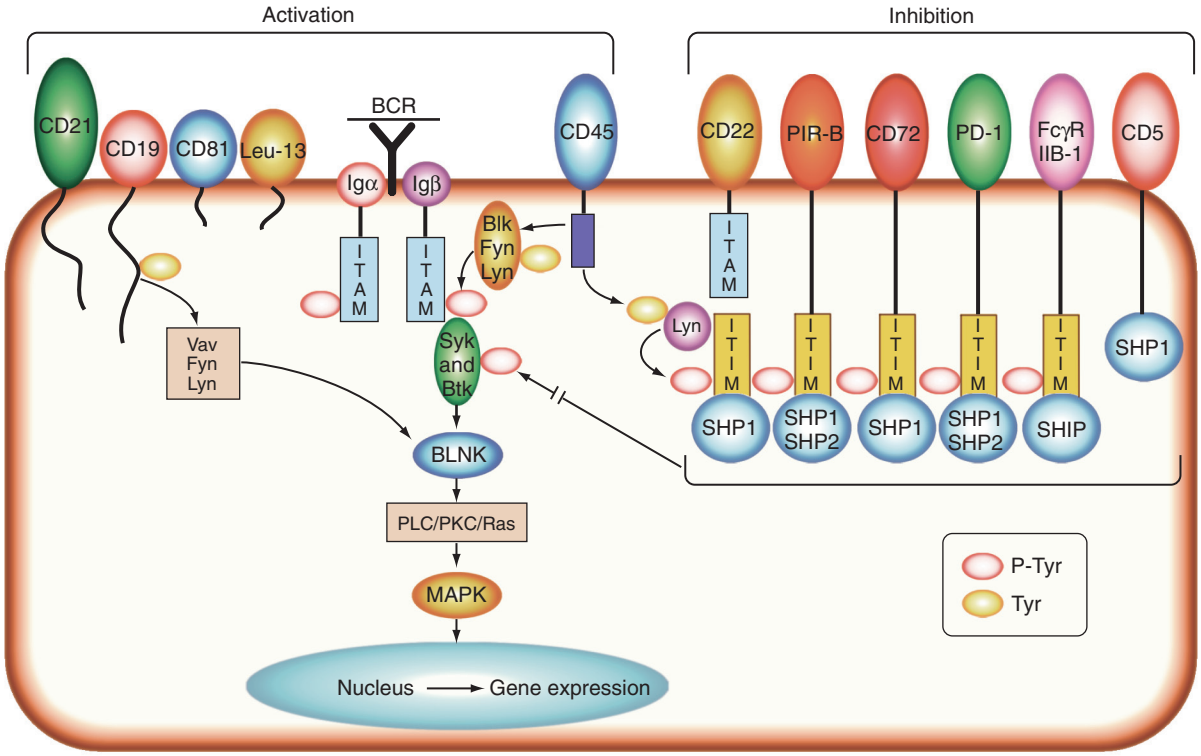

**Figure 13-4** Molecules that regulate the activation state of B cells. Co-ligation of surface immunoglobulin results in tyrosine phosphorylation at specific tyrosine residues present in the immunoreceptor tyrosine activation motif (ITAM) of Igα and Igβ cytoplasmic domains. This phosphorylation occurs after the removal of the inhibitory tyrosine residues of the B cell receptor (BCR)–associated cytoplasmic kinases such as Blk, Fyn, and Lyn, which is mediated by CD45. The phosphorylated ITAMs recruit and activate the Syk and Btk kinases, which in turn activate a series of second messenger pathways (PLC, PKC, and Ras) that result in the upregulation of genes required for B cell activation and survival. Co-ligation of the pre-BCR complex (CD19, CD21, CD81, and Leu-13) results in phosphorylation of tyrosine residues residing in the cytoplasmic domain of CD19. Cytoplasmic kinases including Vav, Fyn, and Lyn become activated and enhance the signaling mediated by the BCR. After the activation of distal mediators of BCR signaling such as PLC, PKC, and Ras, molecules of the mitogen-activated protein kinase (MAPK) pathway become activated and translocate to the nucleus to regulate gene expression. Signals mediated by CD22, PIR-B, CD72, PD-1, FcγRIIB1, and CD5 deliver negative signals that block the activation of distal molecules. After phosphorylation of the immunoreceptor tyrosine inhibition motif (ITIM), present in the cytoplasmic tail of these molecules, the phosphatases SHP1, SHP2, and SH2-containing inositol 5-phosphatase (SHIP) are recruited and activated.

Lyn, it is believed that the ITIM of CD22 is phosphorylated by Lyn, leading to the recruitment and activation of phosphatases such as SHP1 that downregulate the activation cascade.[64]

### FcγRIIB

Simultaneous ligation of both the BCR and FcγRIIB1 sends an inhibitory signal to diminish antigen activation of naïve and memory B cells. This inhibitory signal is activated by the presence of immune complexes and provides a negative feedback mechanism to attenuate an antigen-induced antibody response. After co-ligation of FcγRIIB1 and the BCR, Lyn phosphorylates FcγRIIB1.[65] The SHIP then associates with the FcγRIIB1 and mediates the dephosphorylation of phosphatidylinositol (3,4,5)-triphosphate ($PIP_3$), the major product of PI3K, thus inhibiting the recruitment and activation of Btk and Akt and attenuating BCR signaling.

### CD5

The role of CD5 in B1a cell function is not well understood. After BCR cross-linking, CD5 is thought to mediate signals that induce apoptosis and block proliferation.[66] Cross-linking of CD5 with an anti-CD5 monoclonal antibody results in apoptosis. Some evidence indicates that CD5 recruits the inhibitory protein tyrosine phosphatase SHP1 to its cytoplasmic domain. However, unlike CD22 and FcγRIIB1, CD5 does not contain a consensus ITIM sequence and may recruit SHP1 indirectly.[67] The ligand-binding region of CD5 remains to be elucidated, but recent evidence suggests that CD5 may be a ligand for another negative regulator of BCR signaling, CD72.

### CD72

CD72 is a transmembrane receptor that is expressed as a homodimer. The cytoplasmic tail of CD72 contains ITIMs. Mice with a targeted disruption of the CD72 gene reveal that CD72 plays a negative role in B cell activation, presumably through recruitment of SHP1. The B cell of CD72-deficient mice is similar to that of viable moth-eaten mice with expansion of B1 cells and B cells that are hyperresponsive to BCR cross-linking and are more resistant to BCR-mediated apoptosis.[68] There are several putative ligands for CD72, including CD5 and CD100.

### PIR

Paired Ig-like receptor (PIR)-A and PIR-B are expressed in a pairwise fashion, as the names imply. These receptors are believed to have opposing functions, with PIR-A inducing an activation signal and PIR-B inducing an inhibition signal. The ligands for PIR-A and PIR-B remain to be elucidated. Although little is known about the role of PIR-A in B cell activation, recent data demonstrate that PIR-B plays a role in downregulating B cell responses. The cytoplasmic tail of PIR-B possesses several ITIMs that recruit SHP1. Mice that harbor a targeted disruption of the PIR-B gene exhibit a phenotype similar to mice that are deficient in the other ITIM-bearing inhibitory receptors such as an expansion of B1 cells and B cell hyperresponsiveness.[69]

### PD-1

PD-1 is an inhibitory molecule expressed predominantly on activated B and T cells. The ligand-binding domain binds PD-1L, and the cytoplasmic tail of PD-1 contains ITIMs that recruit SHP2 to attenuate BCR signals. The B cells of PD-1–deficient mice are hyper-responsive to BCR signaling, and these mice display an augmented response to T cell–independent type II antigens. On certain genetic backgrounds, PD-1 deficiency leads to an autoimmune phenotype.[70]

## Phosphatases

In general, intra-cellular signaling is regulated by a balance of phosphorylation and dephosphorylation. Protein tyrosine phosphatases (PTPs) play a major role in restraining the magnitude and duration of BCR signaling; among these, SHP1 is a potent negative regulator. SHP1 is found in association with transmembrane proteins such as CD22, FcγRIIB1, CD5, CD72, and PIR-B. SHP1 antagonizes BCR signaling by countering the action of protein tyrosine kinases.[67] The function of SHP1 has been extensively studied in mice that bear a naturally occurring mutation in the SHP1 gene. Mice with this genetic defect are known as moth-eaten mice because of the appearance of their fur. These mice have a decreased number of conventional B cells and an expansion of B1 cells, and they develop a fatal autoimmune and inflammatory disease.[71] The severe defect in B cell regulation underscores the importance of SHP1 in limiting the extent of BCR signaling. In contrast, the intra-cellular tyrosine phosphatase SHP2, although structurally similar to SHP1, seems to be a positive regulator of BCR signaling because it augments ERK responses.[72] The important role played by PTP in disease is also demonstrated by the discovery that a single mutation in the PTPN22, a protein that regulates Src family kinases, augments the risk of multiple autoimmune diseases.[73]

Another important regulator, SHIP, is an inositol phosphatase that inhibits B cell activation by removing the 5 phosphate from $PIP_3$, a critical component that recruits membrane association of pleckstrin homology (PH) domain containing signaling molecules, including PLCγ2, Btk, and Akt. Similar to SHP1 and SHP2, SHIP is recruited to an ITIM on FcγRIIB after BCR cross-linking. Mice deficient in SHIP display splenomegaly and elevated levels of serum antibody.[74]

## Signal Transduction in Immature versus Mature B Cells

An important event in BCR signaling is the recruitment of signaling components to lipid rafts, which are lipid-rich microdomains of the membrane that serve to bring together requisite signal molecules to facilitate integrated functions in three dimension. After antigen engagement, the BCR translocates into lipid rafts and the BCR signaling cascade ensues because of the clustering of signaling components. In addition to activating signals, however, inhibitory components also localize to lipid rafts. As discussed later, BCR ligation mediates negative selection during the immature and transitional B cell stages and B cell activation during the mature B cell stage. The reason for these two distinct outcomes is not clear because the same signal components are present; however, differences in membrane cholesterol limit recruitment of the BCR to lipid rafts in immature B cells.[75] Evidence also indicates that the signal strength and duration and stage-specific expression patterns of signaling elements differ between immature and mature B cells.[76]

## B Cell Activation

B cells develop without bias for a particular antigenic specificity, ensuring that a diverse repertoire of different Ig molecules is produced. After being stimulated by antigen and accessory cells such as DCs and T cells, antigen-activated B cells undergo clonal expansion; B cells that do not interact with antigen are destined to undergo programmed cell death in a matter of days or weeks. The B1 and B2 cell subsets are regulated by different activation mechanisms and are involved in different immune responses (Table 13-3).

### B1 Cell Activation

B1 cells present in the pleural and peritoneal cavities respond to T cell–independent antigens. There are two classes of T cell–independent antigens: type I, which includes lipopolysaccharide, and type II, which includes large multivalent antigens with repetitive epitopes, often found on the surface of bacteria. T cell–independent antigens can directly activate B cells, resulting in the secretion of antibody. Soluble factors such as IL-5 and IL-10 also appear to be involved in the maintenance and activation of B1 cells.

B1 cells do not require interaction with antigen-specific T cells. However, activated T cells and macrophages may augment B1 cell activation, enhance Ig production, and influence isotype class switching such that B1 cells may also produce IgA and IgG.

### Marginal Zone B Cell Activation

MZ B cells are situated in the marginal sinuses, where Ds and specialized macrophages trap and remove antigen from the circulation. Like B1 cells, many MZ B cells express polyreactive BCRs that are specific for microbial antigens,

**TABLE 13-3** Markers of Human Mature B Cell Subsets

| Characteristic | Naïve | Unswitched Memory | Switched Memory | B1 |
|---|---|---|---|---|
| Surface IgM | High | High | Low | High |
| Surface IgD | Low | Low | High | Low |
| CD5 | + | – | – | –/+ |

including both protein and carbohydrate molecules. If micro-organisms reach the lymphoid organ from the blood, MZ B cells recognizing microbial carbohydrates elicit an innate-like T cell–independent response. MZ B cells can also mount a T cell–dependent response against microbial protein antigens. Soluble factors such as BAFF and T cell–derived cytokines are important for MZ B cell activation. MZ B cell activation can also be enhanced by CD40 ligand expressed on T cells, even though an antigen-specific (cognate) interaction with T cells is not necessary. Although the mechanism is not fully understood, MZ B cells are constitutively partially activated and differentiate rapidly into short-lived antibody-secreting plasma cells after activation by antigen. MZ B cells secrete predominantly IgM and, to a lesser extent, IgG antibodies without an affinity maturation process. Thus these antibodies display low to intermediate affinity.

## Follicular B Cell Activation

Engagement of the BCR by antigen signals the B cells to engulf the antigen, process it intra-cellularly, and express peptide fragments bound to class II MHC molecules on its surface. After the expression of peptide fragments bound to class II MHC molecules, antigen-activated B cells present peptide to primed T helper (Th) cells. B cells and T cells interact through T cell receptor recognition of a peptide-MHC complex on the B cell and through engagement of co-stimulatory molecules B7 and CD40 on the B cell by CD28 and CD40L, respectively, on T cells (Figure 13-5). Expression of the B7 molecule is upregulated on B cells after antigen stimulation. B cell activation during a T cell–dependent immune response also depends on engagement of the CD40 receptor expressed on B cells with the CD40 ligand (CD40L) expressed on T cells.[77] The importance of signal transduction events mediated by CD40-CD40L engagement is evident from studies of patients with X-linked hyper-IgM syndrome, an immunodeficiency disease resulting from a defect in CD40L. These individuals do not mount strong immune responses to T cell–dependent

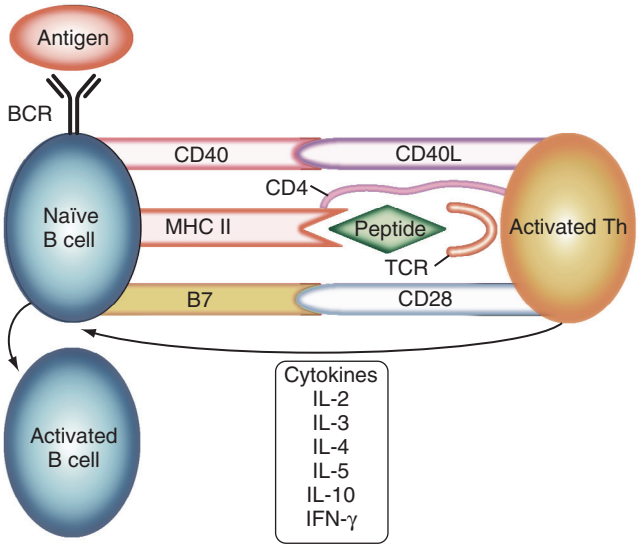

**Figure 13-5** B cells as antigen-presenting cells. Antigen bound to surface immunoglobulin on naïve B cells triggers endocytosis and intracellular processing of the antigen. B cells engage antigen-specific T helper (Th) cells through the recognition of foreign peptide by the T cell receptor (TCR) and through the binding of a conserved region of the class II major histocompatibility complex (MHC) molecule by CD4. Along with antigen binding, co-ligation of CD40 and B7 (expressed on B cells) with CD40L and CD28 (expressed on T cells) provides critical co-stimulatory signals and the secretion of cytokines required for B cell activation. BRC, B cell receptor; IFN, interferon; IL, interleukin.

antigens; they have high concentrations of circulating IgM but only trace amounts of IgG and no affinity maturation of the antibody response. Th cells secrete cytokines such as IL-2, IL-3, IL-4, IL-5, IL-10, IL-17, IL-21 and IFN-γ and provide co-stimulatory signals that are important for B cell maturation and differentiation.[78]

Upon encountering antigen, a naïve B cell with high affinity for the antigen will activate and differentiate to a plasma cell that will secrete IgM or IgG antibodies without somatic mutations. If the activated B cell, however, harbors a receptor with low to intermediate affinity for antigen, the

cell will migrate first to the T cell area of the follicle and will begin the process of creating a GC.[79]

## Germinal Centers

As B cells progress to form GCs, they interact with cognate T cells that are a specialized subpopulation of helper cells known as *T follicular helper* (Tfh) cells. These Tfh cells express CXCR5 and S1P receptor 2 and therefore can migrate to and be retained in the B cell follicle, where, along with the activated B cells, they form discrete structures known as *germinal centers* (GCs). It is in the GC that antigen-activated B cells undergo the process of class switch recombination (CSR) and affinity maturation through somatic hypermutation (SHM), and finally differentiate into memory B cells or long-lived plasma cells.

GCs can be subdivided into separate regions where the different stages of B cell differentiation take place (Figure 13-6). The dark zone is the initial site of rapid proliferation, and B cells within the dark zone are called *centroblasts*. They are derived from a relatively small number of antigen-activated B cells (Table 13-4). Expression of the anti-apoptotic Bcl-2 protein is low in these cells, whereas expression of the proapoptotic Fas protein is upregulated. Low levels of Bcl-2 expression render developing B cells sensitive to apoptosis, but these cells can be rescued by antigen and CD40-CD40L interactions provided by antigen-specific Th cells. When these cells migrate to the light zone, they are termed *centrocytes* and encounter a dense network of FDCs and Tfh (Figure 13-7). B cells that express low affinity BCRs are outcompeted by B cells bearing higher affinity BCRs, whose enhanced antigen acquisition enables them to better interact with cognate Tfh, and thus they are selected to undergo more cell division.[80]

The process of SHM is activated during the centroblast stage. During this process, a nucleotide base-pair change is introduced in the DNA sequence of the variable region of Ig H- and L-chain genes, at approximately $10^{-3}$ per base pair per cell division. The mechanism for SHM is complex and

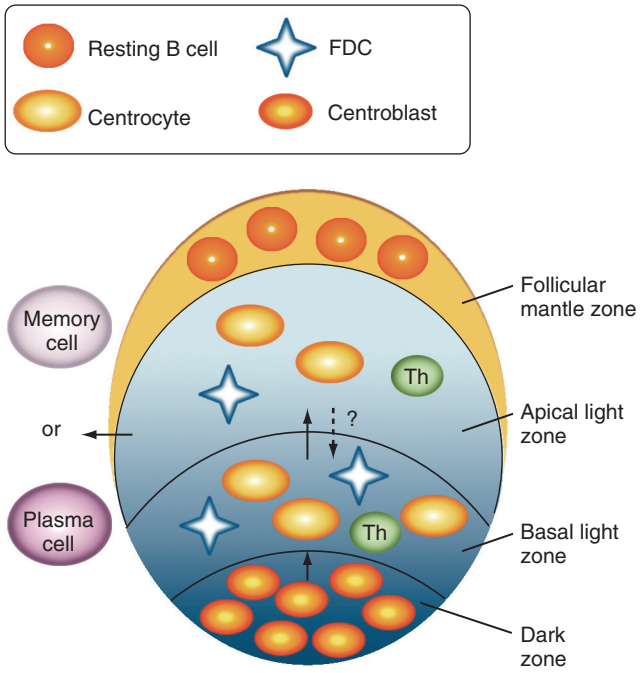

**Figure 13-6** B cell maturation in germinal centers. After exposure to antigen, B cells in the primary follicles form germinal centers or migrate to previously formed germinal centers. Centroblasts located in the dark zone undergo proliferation and acquire somatic mutations. A small number of proliferating centroblasts can give rise to a larger number of centrocytes present in the basal light zone. As these cells pass through a dense network of follicular dendritic cells (FDCs) and T helper (Th) cells, centrocytes bearing surface immunoglobulin receptors with high affinity for antigen undergo positive selection. Centrocytes in the apical light zone are nondividing cells that undergo differentiation into memory B cells or plasma cells. It has been suggested that centrocytes may return to the dark zone, where additional somatic mutations may be acquired. Resting B cells that are not activated by antigen are pushed aside to form the follicular mantle zone.

**TABLE 13-4** Markers of Antigen-Activated B Cells in Secondary Lymphoid Tissue

| Marker | Naïve | Centroblast | Centrocyte | Memory | Plasma |

| Blimp-1 | – | – | – | ? | + |

AICDA, Activation-induced cytidine deaminase; Bcl-2, B cell lymphoma 2; Blimp-1, B lymphocyte–induced maturation protein 1; CD, cluster of differentiation; Ig, immunoglobulin.

*Bcl-2 is expressed in centrocytes only after interaction with follicular dendritic cells.

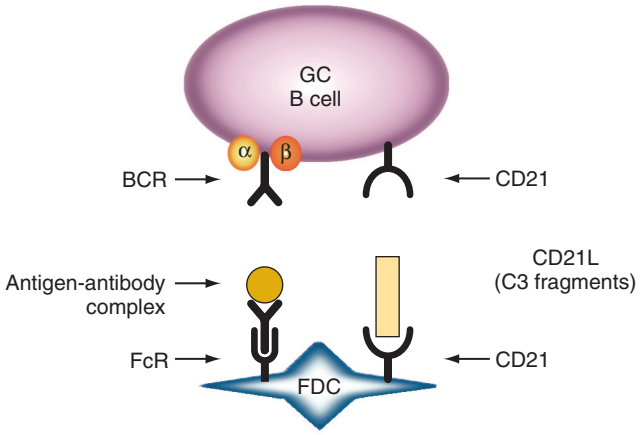

**Figure 13-7** Engagement of B cells with follicular dendritic cells (FDCs). Interaction between FDCs and B cells results in signals that mediate the positive selection of B cells in germinal centers (GCs). Antigen-antibody complexes trapped on the FDC surface deliver a signal to the B cell receptor (BCR). A second signal is delivered by the binding of CD21 on B cells to C3 complement components on the surface of FDCs. FcR, Fc receptor.

requires the enzyme activation-induced cytidine deaminase (AICDA) to target to specific hotspot sequences.[81] The process of SHM is responsible for the affinity maturation of the antibody response. B cell clones that express surface Ig with an increased affinity for antigen are selectively expanded during the affinity maturation process, whereas B cells that express somatically mutated Igs with low affinity for antigen or novel binding to self-antigens are targeted for apoptosis or inactivation. The importance of somatic mutation and affinity maturation during an immune response is underscored by the fact that patients with mutations in the *AICDA* gene are immunocompromised.

AICDA is critical for not only somatic hypermutation but also for CSR. Although expression of IgM and IgD in B cells occurs through alternative splicing of a long transcript that contains coding regions for both the μ and δ chain, expression of any other Ig isotype requires the excision of all the H-chain genes between the recombined V(D)J region and the isotype to be expressed. Isotype switching requires preactivation of the particular H-chain locus to be involved in the recombination event, which is controlled by the cytokine milieu in which the cell is activated. AICDA induces the deamination of cytidine, creating dU:dG pairs (instead of dC:dG pairs) that activate the cellular DNA repair machinery and ultimately create circumstances that favor both CSR and SHM. For CSR, CD40-CD40L interactions and cytokines are also required.

As centroblasts become centrocytes, they require survival signals from FDCs to overcome their low level of Bcl-2 expression and high level of Fas expression. FDCs are stromal-derived cells that trap antigen-antibody complexes by FcγR and complement receptors in bodies known as *iccosomes* (immune complex-coated bodies) on the cell surface. Iccosomes deliver an antigen-specific signal to B cells through the BCR (Figure 13-8). Centrocytes with specificity for antigen on FDCs are saved from apoptosis by upregulation of the Bcl-2 molecule. Engagement of the complement receptors CR1 and CR2 (CD21 and CD35, respectively) on B cells by components of the C3 complement protein (iC3b, C3dg, and C3d) bound to FDCs may mediate a secondary co-stimulatory signal.[82] If centrocytes do not receive these positive selection signals, they rapidly die through a Fas-dependent pathway. Should they receive survival signals, they continue to differentiate into memory B cells or plasma cells.

## Ectopic Lymphoid Structures

Despite being the prototypical structure for the induction of humoral immune responses, GCs are not found exclusively in lymphoid tissue. Ectopic lymphoid structures with GC-like characteristics are present in sites of chronic inflammation such as the synovium in persons with rheumatoid arthritis, pancreatic islands in persons with type 1 diabetes, and salivary glands of persons with Sjögren's syndrome.[83]

These GC-like structures seem to develop as a consequence of chronic inflammation, which leads to the release of soluble mediators such as the chemokines CCL21 and CXCL12 that recruit lymphocytes.[84] These cells, once activated, secrete cytokines such as lymphotoxin that act in a paracrine manner and contribute to the organization of a GC-like structure that includes a dark and light zone with local induction of AICDA. In contrast to the germinal centers of the secondary lymphoid organs, these structures are not encapsulated. The B cells in these structures, therefore, are continuously exposed both to the local antigens that might be absent from the lymphoid organs[85] and to the inflammatory microenvironment that may facilitate bypass of the regulatory points in B cell differentiation, hence contributing to a potential autoimmune bias in these sites. Although no evidence exists that these structures are the underlying cause of any disease, in some diseases they may contribute to tissue pathology and augment the pool of autoreactive plasma and memory cells. Not all ectopic lymphoid foci share characteristics with the GC. It is not known which structures are more damaging to tissue.

## B Cell Differentiation

After antigen activation, B1 and MZ B cells rapidly differentiate into antibody-secreting plasma cells independent of T cell help. This innate-like humoral response generates mostly short-lived plasma cells that produce antibodies with low affinity, but it provides an early and fast protection against blood-borne microbes. It is antigen-activated follicular B cells that generate adaptive antibody responses through a GC reaction that give rise to long-lived memory B cells and plasma cells.

### Memory B Cells

Postgerminal center memory B cells express Ig genes that have undergone CSR and SHM, and in humans they are distinguished by the presence of the marker CD27. The CD40-CD40L interaction contributes to directing GC B cells to mature into long-lived memory B cells. The exact life span of memory B cells is unknown. It has been postulated that these B cells either persist throughout the lifetime of the host[81] or are renewed constantly through either nonspecific stimulation[86] or antigen-specific stimulation.[87]

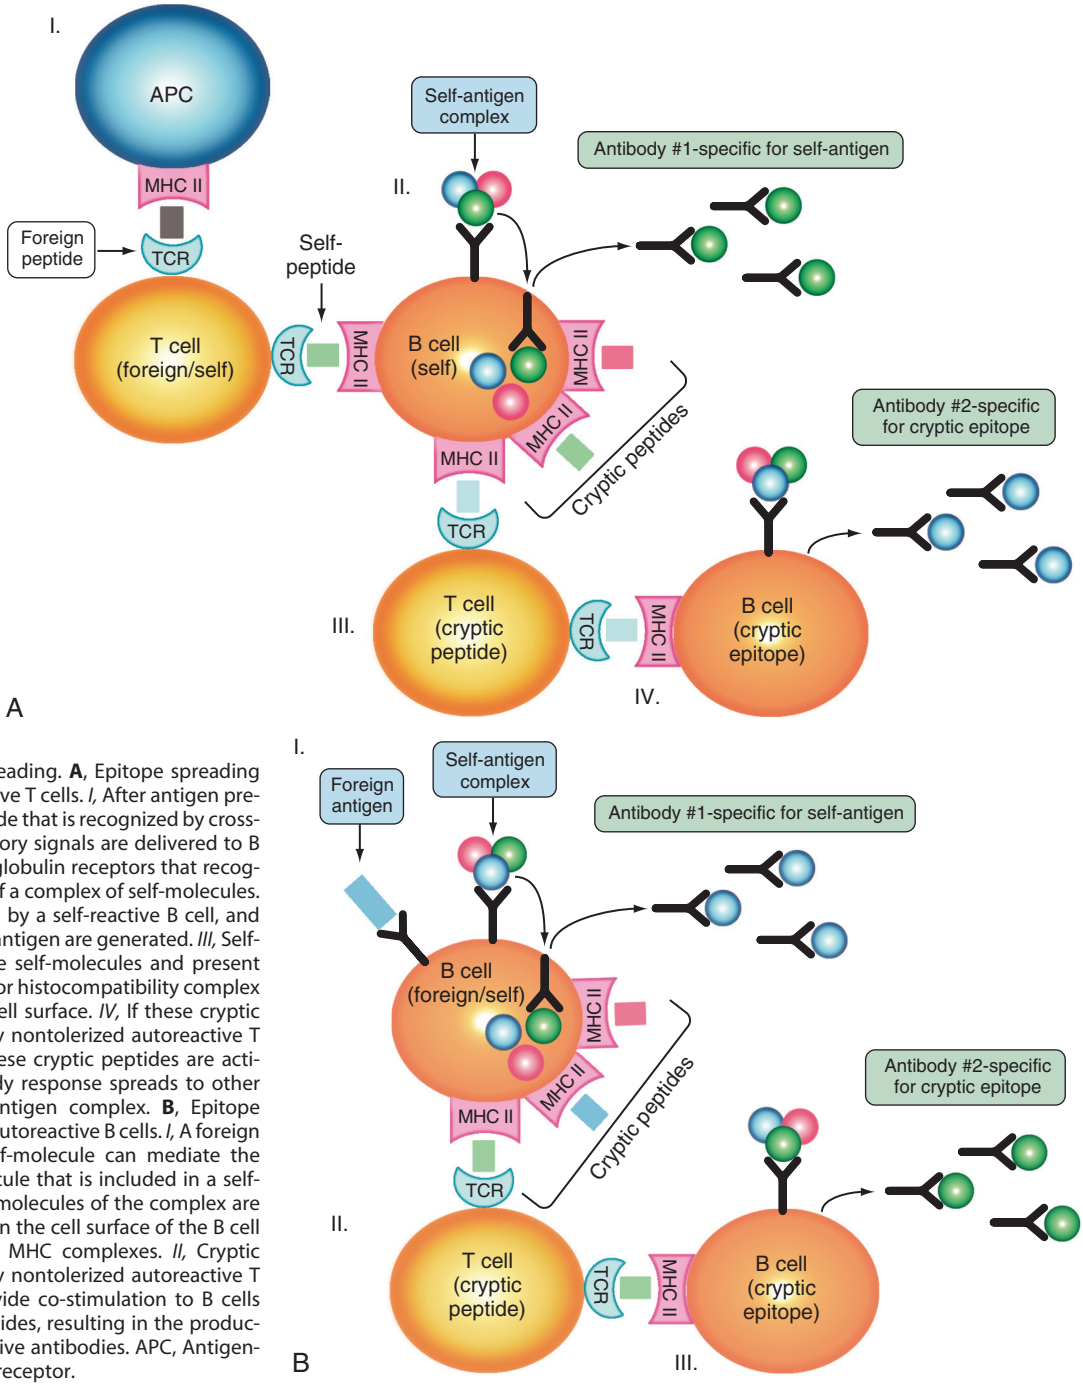

**Figure 13-8** Epitope spreading. **A**, Epitope spreading by activation of cross-reactive T cells. *I,* After antigen presentation of a foreign peptide that is recognized by cross-reactive T cells, co-stimulatory signals are delivered to B cells with surface immunoglobulin receptors that recognize a self-antigen as part of a complex of self-molecules. *II,* The complex is engulfed by a self-reactive B cell, and antibodies specific for self-antigen are generated. *III,* Self-reactive B cells process the self-molecules and present cryptic peptide–class II major histocompatibility complex (MHC) complexes on the cell surface. *IV,* If these cryptic peptides are recognized by nontolerized autoreactive T cells, B cells specific for these cryptic peptides are activated and the autoantibody response spreads to other components of the self-antigen complex. **B**, Epitope spreading by activation of autoreactive B cells. *I,* A foreign antigen that mimics a self-molecule can mediate the endocytosis of a self-molecule that is included in a self-antigen complex. The self-molecules of the complex are processed and expressed on the cell surface of the B cell as cryptic peptide–class II MHC complexes. *II,* Cryptic peptides are recognized by nontolerized autoreactive T cells. *III,* These T cells provide co-stimulation to B cells that recognize cryptic peptides, resulting in the production of additional self-reactive antibodies. APC, Antigen-presenting cell; TCR, T cell receptor.

Memory B cells circulate throughout the body in a quiescent state until specific antigen is re-encountered and triggers a potent secondary immune response. Memory B cells respond to antigen much faster, require lower amounts of antigen, and can even be induced in its absence by soluble mediators such as IL-2 or IL-15, in part because the BCR is already localized to lipid rafts. Subsequently, just like naïve B cells, memory B cells ingest antigen and express peptide–class II MHC fragments. After antigen presentation of peptide to Th cells, memory B cells undergo expansion and may differentiate to plasma cells.

### Plasma Cells

The B cell differentiation cascade ends with the generation of a plasma cell. At the molecular level, the differentiation program is directed by the transcriptional repressor known as *B lymphocyte–induced maturation protein 1* (Blimp-1).[88] Blimp-1 induces a program in which plasma cells lose expression of several markers because they no longer express surface Ig, MHC molecules, or CD20. They initiate increased protein synthesis and secretion and consequently exhibit a large cytoplasm with a well-developed endoplasmic reticulum devoted to antibody production.

Blimp-1 also silences the expression of CXCR5, and thus B cells differentiating into plasma cells exit the lymphoid follicles and migrate to extrafollicular regions of secondary lymphoid tissue or to the bone marrow, where the final stage of plasma cell maturation occurs. B cells in the GC are induced to become plasma cells by IL-5, IL-6, and IL-21. Plasma cells have a variable life span that may be days for short-lived plasma cells that originate extrafollicular responses to years for long-lived plasma cells that arise from the GC response and home to the bone marrow.[89]

The longevity of plasma cells in the bone marrow depends on the presence of a niche that provides the survival factors CXCL12, IL-6, APRIL, and TNF. Cross-linking the FcγRIIb expressed by plasma cells induces apoptosis, a phenomenon that has been credited with pruning the plasma cell repertoire.[6]

### Trafficking of Postimmune Cells

Plasma cells downregulate CXCR5 expression and elevate expression of EBI2, a chemotactic receptor that guides cells to outer follicle areas and extrafollicular regions. Both memory and plasma cells express CXCR4 that directs homing to the bone marrow but also allows localization in lymphoid tissues. Therefore CXCR4-expressing plasma cells can be found surrounding the GC or B cell follicles.[90] A subset of memory cells expresses CXCR3 and therefore migrates toward inflammatory chemokines such as CXCL9 and CXCL10.[91]

### Nonconventional B Cell Activation

Although it is a central paradigm that B cells require cognate antigen for activation, it has also been known for years that infections induce an antibody response in which only a fraction of the responding B cells are specific for microbial antigen. This phenomenon, known as *polyclonal activation*, is induced by several mediators such as superantigen, cytokines, or noncognate T cell co-stimulation and leads to the production of self-reactive antibodies.

B cell superantigens include the *Staphylococcus aureus* protein A (SpA), the protein gp120 of HIV-1, and the erythrocyte membrane protein 1 of *Plasmodium falciparum*. These proteins share the ability to bypass the need to be recognized in the CDRs and bind instead to framework regions common to Ig gene families. They can therefore activate multiple clones; for example, SpA recognizes Igs of the $V_H3$ family that constitutes up to 50% of the IgM repertoire.[92] Although the activation of multiple B cell clones by an organism might be seen as an advantage for the host, polyclonal activation leads to an extrafollicular response that, after a transient hyperglobulinemia, exhausts the B cell pool, leaving a vulnerable organism.

Noncognate activation of B cells clearly occurs in memory B cells that are easily activated by the presence of soluble mediators such as IL-2, IL-15, or CpG (see the Memory B Cells section).[86] In chronic infections, polyclonal activation seems to be a consequence of two nonmutually exclusive mechanisms. The simpler one is bystander activation of noncognate B cells by inflammatory cytokines. The second is $CD4^+$ T cell–mediated co-stimulation. Noncognate B cell activation carries the intrinsic risk of activating self-reactive B cells, as is observed in both experimental and natural infections.[93]

### Mucosal T–Independent Class Switch Recombination

In the mucosa, IgA specific to commensal bacteria is induced through machinery that is T cell independent and occurs outside of organized lymphoid tissue.[94] Because this phenomenon is independent of T cells, other interactions must provide the required signals for CSR. One of the candidate molecules is BAFF (BLyS), which is expressed by DCs in mucosal tissue. BAFF has been shown to induce CSR in B cells in the presence of IL-10 or TGF-β, both of which are present in the mucosal microenvironment.[95]

## REPERTOIRE SELECTION

The ability to discriminate between foreign and self-antigens is as important as the capacity to mount a protective immune response. Any molecule derived from the intracellular or extra-cellular components of the host can be considered self-antigen; the censoring of the responses against these antigens occurs throughout B cell maturation and includes multiple mechanisms in the B cells themselves and in cells that cooperate in their activation and differentiation.

### Tolerance

The random process of V(D)J recombination generates a diverse repertoire of BCRs that recognize virtually all antigens and thus, inevitably, also self-antigens. SHM during GC reactions also give rise to B cells with autoreactive BCRs. These autoreactive B cells have to be purged by a process known as *tolerance*.

Tolerance is achieved through signals provided by the BCR, co-receptors, inflammatory mediators, and metabolic by-products that are integrated by the cell according to its developmental stage. BCR cross-linking during development or in the absence of co-stimulatory signals activates tolerance mechanisms in immature and transitional B cells. The same mechanisms that induce tolerance to self-antigen can induce tolerance to pathogens, and because some autoantigens are sequestered in sites of immune privilege, cells specific to them are not subject to tolerance mechanisms.

The tolerance mechanism activated depends on the stage of the B cell and the strength of the BCR signal delivered by antigen. The strength of the signal depends on the degree of cross-linking of the BCR, which in turns depends on the concentration of self-antigen and the affinity of the antibody for self-antigen. With little receptor cross-linking, because of low antigen concentration or low affinity for antigen, there is no BCR signaling, and the autoreactive B cell is not tolerized. Three mechanisms mediate tolerance: receptor editing, anergy, and deletion. When mechanisms that regulate autoreactive B cells fail, the breakdown of self-tolerance can lead to the development of autoimmune disease.

During B cell development, autoreactive B cells are generated in the bone marrow after V(D)J rearrangement and expression of surface Ig on immature B cells. Because of the vast number of different antibody molecules that can be

formed through the random recombination of H- and L-chain variable region genes and the random association of H and L chains, all individuals generate autoreactive B cells. The tolerance process that prevents the maturation of autoreactive B cells occurs with such efficiency that despite the fact that more than 75% of immature B cells bear receptors with some degree of autoreactivity, about 30% of naïve B cells do so.[96]

### Receptor Editing

A high degree of cross-linking of the BCR during development results in a process known as *receptor editing*. This process involves a secondary gene rearrangement of the H-chain or L-chain genes. Receptor editing requires reactivation of the recombination machinery and re-expression of RAG-1/RAG-2. When successful, receptor editing produces a BCR receptor with low or no affinity to the antigens present in its environment, and the cell is allowed to continue its development. RAG-1/RAG-2 can be seen in some cells in the GC or extrafollicular region as well, and some authors have interpreted this as evidence that receptor editing also occurs later in B cell development.

### Deletion

Extensive BCR cross-linking also leads to apoptosis, thus deleting the autoreactive B cell. This was the first mechanism of tolerance described for B cells[97] and was long believed to be the main mechanism of central tolerance. However, deletion occurs only when cells are not able to decrease their autoreactivity by editing the BCR. In the periphery, deletion occurs if a B cell is extensively activated in the absence of Th cell co-stimulation. Tolerance through deletion is mediated primarily through the activation of a series of endogenous proteases. In B cells the Fas pathway and the Bcl-2 pathway play important roles in regulating apoptosis.

Fas (also known as *CD95* or *Apo-1*), a member of the TNF receptor gene family, and Fas ligand are transmembrane proteins expressed on a variety of cell types. Because Fas ligand is a homotrimeric molecule, it can bind three Fas molecules. Clustering of Fas on the cell surface, which occurs when Fas molecules bind Fas ligand, activates apoptosis.[98] It appears that when B cells engage CD40L expressed on Th cells in the absence of BCR ligation, Fas signaling induces apoptosis.[99,100] Mutations in Fas *(lpr)* or Fas ligand *(gld)* in mice result in a SLE-like syndrome characterized by the production of pathogenic autoantibodies and lymphadenopathy. In humans, similar mutations lead to lymphadenopathy and anti-erythrocyte antibodies, but anti-DNA antibodies and glomerulonephritis are not found in these individuals.[101]

The Bcl-2 gene family is composed of molecules that either protect against or induce apoptosis in many cell types. Relative levels of these molecules dictate life and death of a cell. For example, excess Bcl-2 or Bcl-xL promotes cell survival, whereas excess Bax or Bim induces cell death.[102] Bcl-2 and Bcl-xL are upregulated at critical points during B cell development but can be easily counterbalanced on BCR cross-linking. The fact that certain mouse strains that overexpress Bcl-2 in B cells produce autoantibodies highlights the importance of apoptosis in tolerance.[103]

### Anergy

Anergy is a hyporesponsive state considered to be induced in immature B cells when they undergo a modest degree of BCR cross-linking. Anergic B cells downregulate surface Ig receptors and display a desensitization of the BCR, blocking activation of downstream signaling. Anergic B cells are short-lived. Goodnow and colleagues[104] performed classic studies on B cell tolerance induction in mice engineered to express an anti–hen egg lysozyme (HEL) antibody, along with soluble HEL, to act as a self-antigen. In the anti-HEL transgenic mouse model, B cells that encounter soluble, monovalent HEL are anergized. These B cells populate secondary lymphoid tissue but do not secrete anti-HEL antibody and are not recruited into B cell follicles. This phenomenon is known as *follicular exclusion*.[105]

Although anergy implies that the cells are not activated through BCR engagement, they *can* be activated by non–antigen-specific T cell co-stimulation, lipopolysaccharide, or IL-4. Exposure of anergic B cells in vivo to multivalent antigen in the presence of activated Th cells may also lead to their activation.[106] Consequently, it has been suggested that anergic B cells may serve as a potential source of autoantibody and may be activated in inflammatory conditions. Recently, it has been shown that B cells can be blocked from activation if they are chronically exposed to antigen and IL-6. If IL-6 is removed from the microenvironment, those chronically activated B cells will secrete antibody.

## B Cells as Immune Regulators

B cells produce cytokines in response to their environment. Several subsets of B cells have been reported to be able to suppress autoimmunity, including $CD1d^{hi}CD5^{+}$ B cells and transitional B cells. All these B regulatory cells (Bregs) produce IL-10 to suppress immune responses.[107] The function of Bregs depends on stimulation through BCR and CD40. In healthy persons, Bregs secrete IL-10 in response to CD40 engagement, whereas the equivalent population in patients with SLE fails to do so.[108] Bregs are also able to mediate immunosuppression through an IL-10–independent mechanism. Recent studies have identified IL-35 as an additional effector molecule for Breg function.[109,110] Some IL-35–producing Bregs express CD138 and Blimp-1. Thus, activated B cells and plasma cells play an important role in regulating immune responses. These Bregs not only harness autoimmunity but also restrain immune responses against microbial infection.

## Regulation by Small Molecules

Beyond the classic activators and regulators, the molecules described in the following sections play a particularly important role in the biology of B cells and are highlighted given their potential as biomarkers and therapeutic agents.

### Vitamin D

Vitamin D is acquired from the diet or synthesized in the skin, followed by a conversion into a biologic product in the liver and kidney. The active metabolite,

1,25-dihydroxyvitamin $D_3$, has been shown to decrease activation and proliferation of B cells, as well as differentiation to plasma cells. Circulating levels of vitamin D tend to be decreased in patients with autoimmune disease; whether this phenomenon contributes to the disease process is not known.

### Estrogens

The role of estrogens in B cell–mediated autoimmune diseases has long been suggested by the female gender predominance within autoimmune diseases and may reflect a variety of effector mechanisms. However, estrogens have been shown to modify the B cell repertoire, allowing survival of autoreactive B cells, and to alter the peripheral compartments in mice.[111]

### Leptin

Although its first described role was as an endocrine hormone with a primary role in the control of metabolism, leptin was later shown to exhibit immune regulatory effects. For example, a murine model of experimentally induced arthritis is attenuated in leptin receptor–deficient mice.[112] More recently, it has been shown that leptin promotes B cell survival and proliferation through induction of Bcl-2 and cyclin D1.[113]

## B CELL–MEDIATED AUTOIMMUNITY

B cell–mediated autoimmunity is the consequence of the production of self-reactive antibodies. We have detailed multiple mechanisms operating throughout B cell maturation and differentiation that are designed to avoid autoreactivity. The failure of only one tolerance checkpoint rarely leads to autoimmune disease[114]; it may, however, increase the level of circulating autoantibodies, without clinical disease.

The generation of a B cell–mediated autoimmune disease must involve (1) the generation of B cells bearing autoreactive BCRs; (2) failure of mechanisms that in the normal event will abrogate their maturation to short- or long-lived plasma cells; and (3) tissue malfunction induced by the autoantibody that leads to clinical symptoms.

### Origin of Autoreactive B Cells

Theoretically, autoreactive cells can arise from any B cell subpopulation. In mice, B1 cells that bear BCRs with low affinities but high polyreactivity produce autoantibodies, but these autoantibodies help remove cellular debris and can protect the body from pathogenic autoreactivity. In addition, evidence indicates that MZ B cells secrete autoantibodies, which may also provide a physiologic rather than pathologic function.

### Autoreactivity in the Preimmune B Cell Repertoire

Studies of the reactivity of human B cells have shown that in the healthy peripheral B cell compartment, about 30% of the naïve B cells bear some degree of autoreactivity; however, few of those can be considered potentially pathogenic given their low affinity for autoantigen.[96] In persons with SLE, the frequency of autoreactive cells is as high as 50% in the naïve B cell population[115]; the frequency is greatest when disease is active and diminishes during periods of disease quiescence,[116] demonstrating that an inflammatory milieu may alter B cell selection.

### Autoreactivity in the Postimmune B Cell Repertoire

Most of the autoantibodies in patients with autoimmune disease are generated through GC reaction because they have undergone CSR and display extensive somatic mutation. This observation suggests that the GC does not possess a fail-proof mechanism to effectively purge mutated autoreactive cells, although post-GC receptor editing and deletion of autoreactive B cells has been shown to occur. The understanding of the tolerance mechanisms that prevent the generation of autoreactive memory B cells and plasma cells is still incomplete.

### Molecular Triggers of Autoimmunity

Several prevailing theories attempt to explain the activation and expansion of autoreactive B cells that should normally be silenced. Autoimmunity is thought to arise by a combination of environmental factors such as infectious agents that initiate an autoimmune response and genetic defects that alter B cell regulation. Proposed models for autoimmunity include (1) cross-reactivity of foreign antigen with self-antigen, (2) inappropriate co-stimulation, and (3) altered thresholds for BCR signaling.

Much of our understanding of the breakdown of self-tolerance and the progression of autoimmunity comes from the examination of mouse models. Autoimmune mouse models can be divided into two broad categories: induced autoimmunity and spontaneously occurring autoimmunity. Even though the progression of autoimmunity in humans is thought to be a highly complex process that involves multiple genetic and environmental factors, these animal models have provided much information about the molecular events that lead to a loss of self-tolerance.

#### Molecular Mimicry

One proposed model for the initiation of autoreactivity is that cross-reactive anti-self, anti-foreign B cells escape central tolerance because self-antigen is present at too low a concentration to trigger tolerance induction or because the affinity of the antibody for autoantigen is below the signaling threshold. These B cells become activated in the periphery by foreign pathogens resembling self-antigen and produce antibodies that bind both foreign and self-antigen. This cross-reactivity is known as *molecular mimicry*, and it is a popular model to explain the induction of many autoimmune disorders.[117] Once the pathogen is cleared, the autoantibody response is usually diminished because antigen-specific T cell help is no longer present, unless a high number of long-lived plasma cells have been generated. In the case of autoimmune-prone individuals, it is proposed that intrinsic B cell defects prevent the

**TABLE 13-5** Evidence for Antibody Cross-Reactivity between Foreign and Self-Antigens

| Foreign Antigen | Self-Antigen |
|---|---|
| Yersinia, Klebsiella, Streptococcus[a] | DNA |
| Epstein-Barr virus nuclear antigen 1[a] | Ribonucleoprotein SmD |
| Streptococcus M protein[b] | Cardiac myosin |
| Coxsackie B3 capsid protein[c] | Cardiac myosin |
| Klebsiella nitrogenase[d] | Human leukocyte antigen B27 |
| Yersinia lipoprotein[e] | Thyrotropin receptor |
| Mycobacteria heat shock protein[f] | Mitochondrial components |
| Escherichia, Klebsiella, Proteus[g] | Acetylcholine receptor |
| gpD derived from herpes simplex virus[g] | Acetylcholine receptor |

Autoimmune disorders exhibiting cross-reactive antibodies: *a*, systemic lupus erythematosus; *b*, rheumatic fever; *c*, myocarditis; *d*, ankylosing spondylitis; *e*, Graves' disease; *f*, primary biliary cirrhosis; *g*, myasthenia gravis.

downregulation of autoantibody production, even after foreign antigen clearance. Several data support molecular mimicry as a trigger for B cell–mediated autoimmunity in some instances; for example, antibodies to infectious agents have been identified that cross-react with self-molecules associated with specific autoimmune diseases[118] (Table 13-5). Intriguing examples include the cross-reactivity observed between the M protein of group A *Streptococcus* and cardiac myosin in rheumatic heart disease and the cross-reactivity between *Campylobacter* and aquaporin.

Because both nonautoimmune and autoimmune-prone persons have the capacity to generate autoantibodies, it is unlikely that cross-reactivity between foreign and self-antigens is solely responsible for breakdown of tolerance. A plausible explanation is that foreign antigen acts as a molecular trigger to initiate an immune response to self-molecules, and a defect in the mechanism that regulates B cell activation leads to the propagation of an autoimmune response.

In general, an initial immune response is generated against a dominant set of epitopes, followed by a later response to secondary or "cryptic" epitopes, a process known as *epitope spreading*.[119] Epitope spreading is an important aspect of a protective immune response because the ability to recognize multiple antigenic determinants increases the efficiency of the neutralization and removal of pathogens. When an autoimmune response has been triggered, epitope spreading can lead to the production of additional autoantibodies with specificity for multiple self-antigens. There are several proposed mechanisms by which epitope spreading triggers a cascade of T and B cell activation. For instance, antigen-presenting cells may present a foreign peptide that mimics a self-peptide to T cells (see Figure 13-8A). Such cross-reactive T cells become activated and provide co-stimulation to autoreactive B cells that recognize self-antigen, which results in the production of autoantibodies specific for the antigen recognized by the T cell. After internalization of the self-antigen by the autoreactive B cells, the autoantigen is processed and new cryptic epitopes of the self-antigen are presented to T cells. A B cell binding to the self-antigen internalizes not only that self-antigen but also any complex of molecules that includes the self-antigen. The B cell may, therefore, present cryptic epitopes of many self-antigens and activate autoreactive T cells representing multiple autospecificities. In the periphery, T cells are present that have not been tolerized to these (cryptic) epitopes and thus are activated by self-peptide. These activated T cells in turn help provide co-stimulation and activate other autoreactive B cells.

Alternatively, cross-reactive B cells may be activated first after exposure to foreign antigen and T cell help (see Figure 13-8B). These B cells internalize self-antigen and present cryptic peptides to T cells that have not been tolerized, leading to activation of autoreactive T cells and initiation of the cascade. Thus molecular mimicry and epitope spreading could lead to the activation of T cells and B cells specific for multiple autoantigens as long as the autoantigens form a complex in vivo.

### Supraoptimal B Cell Co-Stimulation

It is evident that co-stimulatory signals provided by T cells play a critical role in B cell activation. Therefore inappropriate co-stimulation may lead to the propagation of an immune response directed against a self-antigen. The interaction between B7 on B cells and CD28 on T cells is crucial for the activation of antigen-specific T cells and B cells. When a genetically engineered protein that inhibits B7-CD28 interactions is administered to autoimmune mice, progression of disease is blocked.[120] Reciprocally, autoreactive B cells present in mice that constitutively overexpress B7 are not sensitive to Fas killing, and the mice display high serum autoantibody titers.[118] Overexpression of CD40 or CD40L may also activate autoreactivity. In vitro studies have demonstrated that CD40-CD40L ligation in the presence of IL-4 activates anergic cells. It has been suggested that CD40L may be overexpressed in lymphoid cells of patients with SLE.[5,121]

Roquin-1/RC3H1, a putative ubiquitin E3 ligase, regulates differentiation of Tfh. Roquin-1 is an RNA binding protein that mediates mRNA degradation.[122] It represses the expression of multiple inflammatory cytokines, including ICOS, a co-stimulatory molecule that plays an important role in Tfh development and function. Tfh cells provide strong co-stimulation in the GC. Mice harboring a mutation in the gene encoding Roquin display high-affinity dsDNA antibodies as a result of increased numbers of Tfh and GC B cells.[123]

Interferon regulatory factor-4 binding protein (IBP) has also been shown to regulate T cell co-stimulatory signals.[124] IBP is an activator of Rho guanosine triphosphatases (GTPases) and is recruited to the immunologic synapse after T cell receptor cross-linking to mediate the reorganization of the cytoskeleton. Mice deficient in IBP exhibit an autoimmune phenotype characterized by the production of dsDNA antibodies and glomerulonephritis. IBP plays an important role in the survival and effector function of memory T cells. In addition, IBP sequesters the transcription factor IRF4, thus preventing it from turning on expression of IL-17 and IL-21.[125]

TLRs belong to a family of pathogen recognition receptors that initiate innate immune responses to various

components of pathogens. TLRs are expressed on the cell surface or are localized in the endosomes. Thus TLR4 on the plasma membrane binds bacterial lipopolysaccharides and endosomal TLR7 and TLR9 recognize RNA and hypomethylated CpG-containing nucleic acid sequences, respectively, within B cells. Beside their role in DC maturation and T cell activation and differentiation, TLRs have been shown to be directly involved in multiple steps of antibody responses. Some T cell–independent antigens, such as LPS, engage both BCRs and TLR signaling pathways that induce strong B cell activation. During a T cell–dependent response, co-stimulation of TLR enhances BCR-mediated uptake of antigen and boosts AICDA induction for CSR and GC reactions. TLR activation has also been linked with chronic inflammation and autoimmune diseases. Numerous studies suggest that engagement of the BCR and TLR with immune complexes containing nuclear antigens triggers the activation of anti-nuclear B cells, implying that TLR7 and TLR9 can function to enhance the activation of autoreactive B cells under some circumstances.[126-128]

### B Cell Signaling Thresholds

The effects of altering the threshold for BCR signaling have been demonstrated in several mouse models. In transgenic mice that overexpress the BCR co-receptor complex component CD19, anergic B cells are activated and secrete autoantibody.[129] This result suggests that a decrease in the minimal requirement for antigen engagement of the BCR can lead to inappropriate activation of autoreactive B cells. Viable moth-eaten mice also develop an autoimmune syndrome due to a naturally occurring deficiency in the SHP1 phosphatase, a potent negative regulator of BCR signaling.[71] In these mice, B1 cells are responsible for the production of IgM anti-DNA antibodies. Transgenic mice deficient in other signaling molecules that alter threshold activation such as CD22[62] and Lyn[65] also produce autoantibodies. Thus, lowering thresholds for antigen-induced B cell activation can lead to the activation of autoreactive B cells.

## CONCLUSION

The generation of a diverse repertoire of antibody molecules provides an important line of defense against microbial infections. The immune system is exquisitely controlled at multiple levels to allow the maturation of B cells that produce protective antibodies while attempting to avoid the production of autoantibodies (Figure 13-9). Only a small percentage of B cell precursors generated completes the maturation pathway. During the pro-B and pre-B cell stages of development, B cells with aberrantly rearranged H- or L-chain genes are eliminated. As the remaining precursor cells transit into the immature B cell stage, they are subject to negative selection; that is, immature B cells with

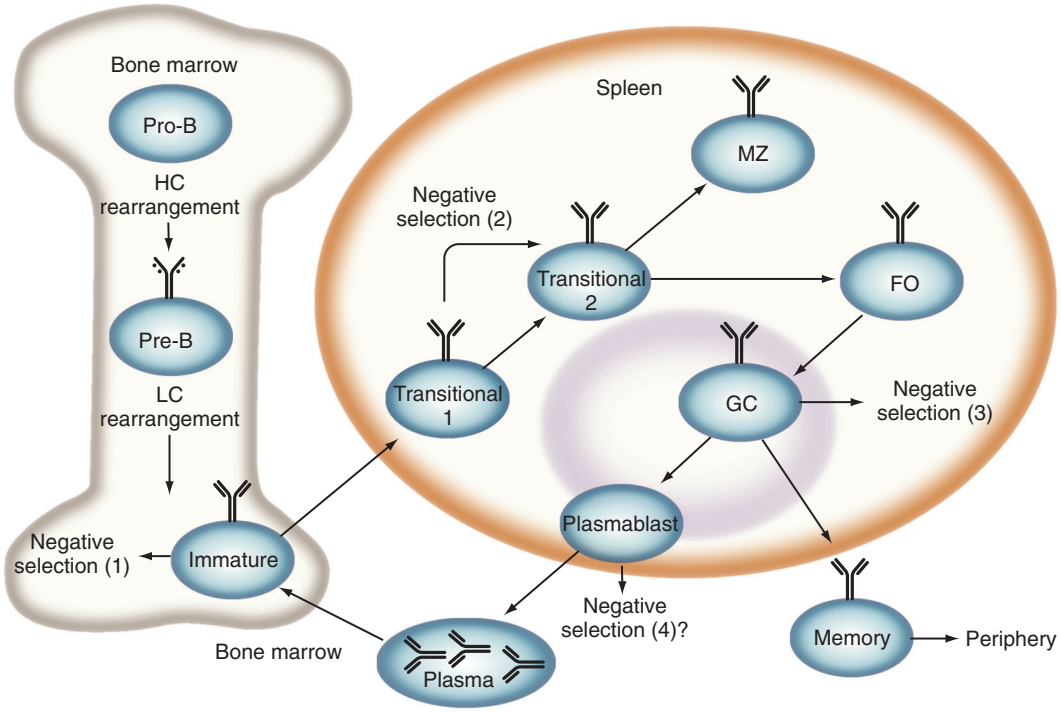

**Figure 13-9** Selection checkpoints during B cell maturation. Autoreactive B cells can be censored at multiple developmental checkpoints: *(1)* After surface expression of surface immunoglobulin, immature B cells that encounter autoantigen in the bone marrow are subject to negative selection. *(2)* B cells that are not eliminated in the bone marrow may undergo negative selection during the transitional B cell stage. Transitional B cells that emerge from this development stage give rise to follicular (FO) or marginal zone (MZ) B cells. Follicular B cells activated by antigen and the help of cognate T cells progress to the germinal center (GC) B cell stage. *(3)* Germinal center B cells that acquire high affinity for autoantigen by the process of somatic hypermutation may be eliminated in the germinal center to block their further maturation into long-lived plasma cells or memory cells. *(4)* There is evidence that autoreactive plasmablasts may also be subject to negative selection. Long-lived plasma cells that emerge from the selection process home primarily to the bone marrow, and memory B cells circulate throughout the periphery. HC, Heavy chain; LC, light chain.

autospecificity are either deleted or inactivated, whereas nonautoreactive B cells are released into the periphery. B cells that are stimulated by foreign antigen are selectively expanded and undergo further Ig gene diversification in peripheral lymphoid tissue. During this stage of development, B cells that express high-affinity BCRs undergo positive selection, whereas B cells with a diminished affinity or those that have acquired autoreactivity are eliminated. B cells that pass through these critical developmental checkpoints differentiate into long-lived memory B cells or plasma cells. The underlying causes of B cell–associated autoimmunity are not fully understood, but just as there are multiple checkpoints for the survival or activation of autoreactive B cells, it seems likely that multiple defects in the regulatory mechanisms that control B cell maturation and differentiation contribute to autoimmune disease.

CHAPTER 14

# Fibroblasts and Fibroblast-like Synoviocytes

Christopher D. Buckley • Andrew Filer

**KEY POINTS**

- Fibroblasts are programmed epigenetically to determine the unique structure and function of different organs and tissues. However, these unique features might contribute to organ-specific disease.
- Tissue fibroblasts may be recruited from a number of sources and cell types including the bone marrow, blood, and local stromal cells and act as organ-specific innate immune sentinel cells.
- Under inflammatory conditions, fibroblasts become key immune system players by recruiting and modulating the behavior and survival of infiltrating immune cells.
- Fibroblasts can be programmed epigenetically through exposure to inflammatory and environmental stress such that they inappropriately prolong inflammation, which becomes persistent.
- Within the synovium, persistent abnormal behavior of fibroblasts results in continued damage to vital joint structures such as cartilage and bone, which, if untreated, will result in deformity and functional impairment.

## WHAT IS A FIBROBLAST?

The architecture of organs and tissues is closely adapted to their function in order to provide microenvironments in which specialized functions may be carried out efficiently. The nature and character of such microenvironments are primarily defined by the stromal cells that reside within the tissues. The most abundant cell types of the stroma are fibroblasts, which are responsible for the synthesis and remodeling of extra-cellular matrix (ECM) components. In addition, their ability to produce and respond to growth factors and cytokines allows reciprocal interactions with adjacent epithelial and endothelial structures and with infiltrating leukocytes. Fibroblasts also integrate microenvironmental stimuli such as oxygen tension and pH. As a consequence, fibroblasts play a critical role during tissue development and homeostasis and are often described as having a "landscaping" function.

### Fibroblast Identity and Microenvironments

Tissue-resident macrophages in the liver (Kupffer cells) and lung (alveolar macrophages) perform very different functions compared with macrophages in the brain (glial cells) or skin (Langerhans cells), yet they are all members of the monocyte/macrophage family. Until recently fibroblasts had been thought of as ubiquitous, generic cells with a common phenotype even within different tissues. However, we now know that fibroblasts from different organs are more like their macrophage counterparts, with unique morphologic features and repertoires of ECM proteins, cytokines, co-stimulatory molecules, and chemokines specialized to the different microenvironments in which they are found. This characterization also extends to their function as "immune sentinel" cells, expressing innate immune system pattern recognition receptors such as Toll-like receptors (TLRs), which trigger a pro-inflammatory response when ligated by bacterial or viral determinants.

Examination of fibroblast transcriptional profiles with use of microarray techniques reveals that fibroblasts retain a strong memory of their anatomic position and function in the body. Early studies demonstrated that fibroblast transcriptomes (i.e., the global picture of transcribed genes measured using microarrays) could be clustered into peripheral (synovial joint or skin fibroblasts) versus lymphoid (tonsil or lymph node) groups according to their organ of origin, with the potential to shift their transcriptional profiles upon exposure to inflammatory mediators such as tumor necrosis factor (TNF), interleukin (IL)-4, or interferon (IFN)-γ. More extensive analysis of expression profiles from primary human fibroblasts by Rinn and colleagues[1] has shown large-scale differences related to three broad anatomic divisions: anterior-posterior, proximal-distal, and dermal-nondermal. Genes involved in pattern forming, cell signaling, and matrix remodeling were found to predominantly account for these divisions.[1] The gene expression profile of adult fibroblasts may therefore play a significant role in assigning positional identity within an organism.

More recently, it has become clear that these stable changes in gene transcription are brought about through epigenetic activation and silencing of the HOX family of landscaping genes.[2] Such epigenetic patterning, whereby covalent modifications are made to regulatory regions of DNA or to the histones around which the DNA is wrapped in order to control access of transcriptional complexes, is a prototype for the stable changes that are also seen in fibroblasts. Epigenetic modifications result in stable changes in gene expression that persist over cellular generations in the absence of mutation of the primary DNA sequence and therefore drive the persistence of disease, as is described in more detail in Chapter 22.

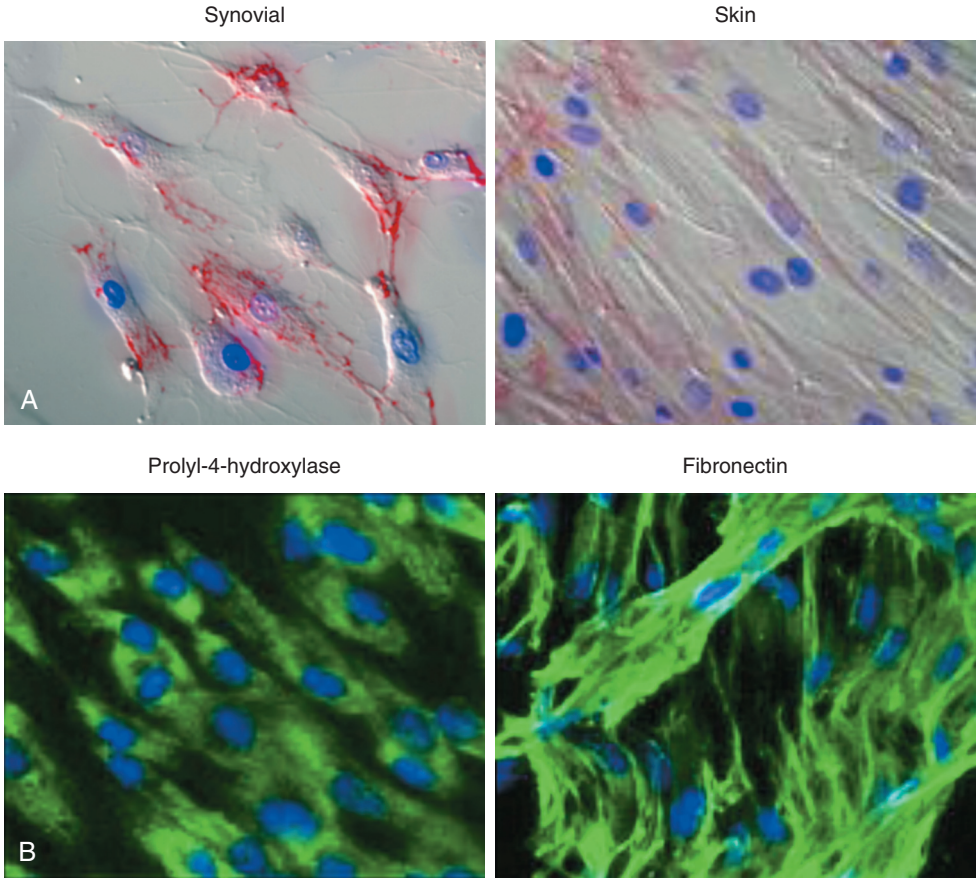

**Figure 14-1** Fibroblast phenotype. **A,** Staining and differential interference contrast microscopy of live fibroblast cells in culture illustrating typical morphologic features and marked differences between synovial fibroblasts of the rheumatoid arthritis joint and skin fibroblasts. Red stain (fibronectin) demonstrates matrix production. Blue stain indicates nuclei. **B,** Stromal cell status is confirmed by fluorescence microscopy of cells showing collagen synthetic enzymes (prolyl-4-hydroxylase) within and matrix production (fibronectin) on the surface of skin fibroblasts.

## Embryologic Origins

The problem of distinguishing fibroblasts of differing origin or maturity has historically been difficult because of a lack of specific cell surface markers. Whereas cluster of differentiation (CD) markers have revolutionized the isolation and study of leukocyte subsets, relatively few, poor-quality discriminatory markers have been identified that allow the identification of fibroblast subpopulations. Therefore fibroblasts traditionally have been identified by their spindle-shaped structure (Figure 14-1), elaboration of ECM, and lack of positive markers for endothelium, epithelial, and hemopoietic cells.

However, growing evidence indicates that fibroblasts are not a homogeneous population but exist as subsets of cells, much like tissue macrophages and dendritic cells (DCs). It is likely that connective tissue contains a mixture of distinct fibroblast lineages with mature fibroblasts existing side by side with more immature fibroblasts that are capable of differentiating into other connective tissue cells. Recent studies have begun to identify novel markers that demarcate distinct subpopulations of stromal cells during development and have the potential to act as markers for different subpopulations of fibroblasts, each with different roles. Such markers include smooth muscle actin, which marks out a population of secretory, activated cells termed *myofibroblasts*, and more recently discovered markers such as CD248 and gp38 (podoplanin) (Table 14-1[3-14]; also see later discussion). Fibroblasts have been defined in terms of their embryologic origins and lineage relationships and are generally considered to be mesenchymal in origin. However, cell populations that appear to blur the distinction between hemopoietic and nonhemopoietic populations have now been identified. In addition, other unexpected shifts in lineage have been reported, including differentiation from neural stem cells into myeloid and lymphoid hemopoietic lineage. Classification by such lineages is therefore becoming increasingly untenable.

## Origins of Fibroblasts in Tissue

Both inflammation and wound healing are characterized by the formation of new tissue. However, recent findings suggest that the new cells that form the remodeled tissues might not be derived from the proliferation of resident cells in the adjacent noninjured tissue, as was previously assumed. This finding is important because in both rheumatoid arthritis (RA) and fibrotic pathologic conditions, fibroblasts accumulate in excessive numbers despite apparently low proliferative rates. The principle origin for fibroblasts is from primary mesenchymal cells, and upon appropriate stimulation, fibroblasts can proliferate locally to generate

**TABLE 14-1** Synovial Stromal Markers and Their Geographic and Functional Significance

| Marker | Associated Cell Type | Synovial Location | Functional Significance |
|---|---|---|---|
| CD55 | Fibroblast-like synoviocyte | Lining layer | Receptor/ligand for synovial macrophage CD97[3] |
| VCAM-1 | Fibroblast-like synoviocyte | Lining layer | Activated lining layer fibroblasts; adhesion molecule[4] |
| α-SMA | Myofibroblast | Variable, minority subpopulation | Secretory, profibrotic fibroblast[5] |
| CD248/endosialin | Pericyte | Sublining fibroblasts, pericytes | Acute inflammation,[6] cancer and vasculogenesis[7] |
| gp38/podoplanin | Pericyte and lymphoid endothelium | Lining layer fibroblasts, pericytes, lymphoid endothelium | Structural, proangiogenic lymph node role[8]; promotes motility in cancer[9] |
| 5B5/prolyl-4-hydroxylase | Broad fibroblast marker in vivo | Lining and sublining cells | Marks collagen synthetic machinery[10] |
| S-100A4/FSP-1/Mts-1 | — | Lining and sublining cells, invasive regions | Cancer, invasiveness roles via motility and impaired apoptosis[11] |
| FAP | Associated with α-SMA$^+$ fibroblasts[12] | Lining layer | Role in cancer fibroblasts,[13] protective if ectoenzyme blocked in rheumatoid arthritis[14] |

α-SMA, α-Smooth muscle actin; FAP, fibroblast activation protein; VCAM-1, vascular cell adhesion molecule-1.

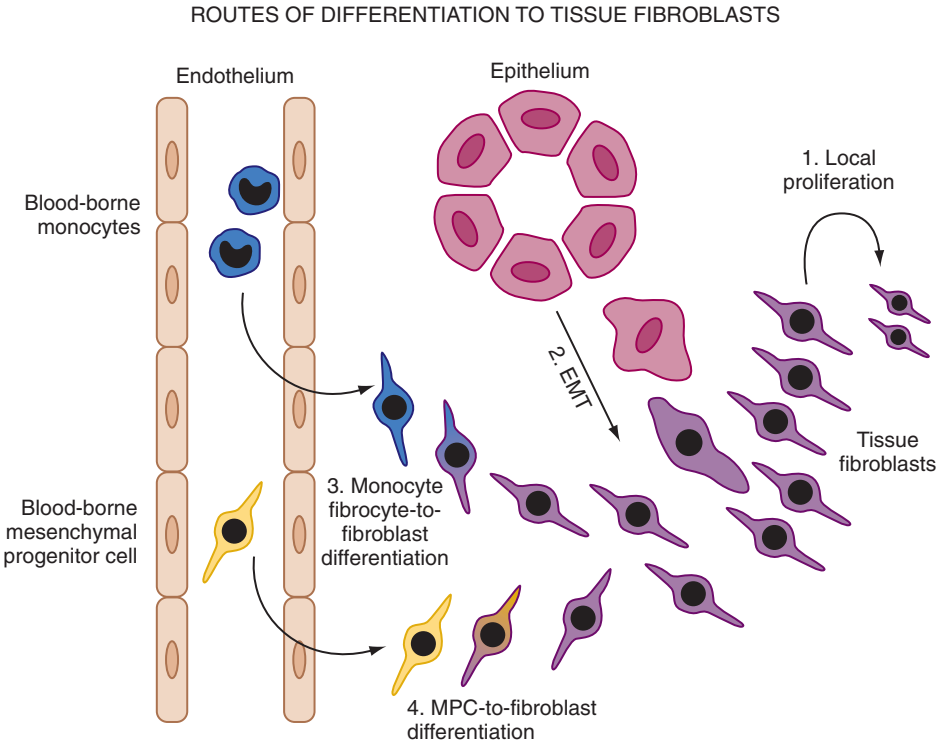

**Figure 14-2** Routes of differentiation to tissue fibroblasts. In response to wounding or inflammation, increased numbers of fibroblasts are produced within tissue. *1,* Fibroblasts can proliferate locally to generate new fibroblasts. *2,* The transition of epithelial to stromal cell populations occurs in cancer and diseases of the lung, kidney, and possibly the synovium. *3,* Fibrocytes arise from the monocyte population in blood and then differentiate toward fibroblasts in tissue. *4,* Blood-borne mesenchymal progenitor cells (MPC) may be recruited to tissues and undergo local differentiation to tissue fibroblasts. EMT, Epithelial to mesenchymal transition.

new fibroblasts; however, although an increase in fibroblast numbers caused by local proliferation does occur, fibroblasts also may arise from other sources (Figure 14-2). The first of these sources is local epithelial to mesenchymal transition (EMT). EMT is an essential, physiologically important developmental mechanism for diversifying cells in the formation of complex tissues. However, fibroblasts also appear to be derived by this process in adult tissue after epithelial stress such as inflammation or tissue injury. EMT both disaggregates epithelial cells and reshapes them for movement. The epithelium loses polarity as defined by the loss of adherens junctions, tight junctions, desmosomes, and cytokeratin intermediate filaments. Epithelial cells also rearrange their F-actin stress fibers and express filopodia and lamellipodia. A combination of cytokines and matrix metalloproteinases (MMPs) associated with digestion of the basement membrane is believed to be secreted and is important in the process. The transition of epithelial to mesenchymal cell populations has been shown to occur in cancer and in diseases of the lung and kidney, in which the

process has been implicated in fibrotic disease.[15] Early evidence suggests that a similar process may occur within the RA synovium.[16]

An alternative explanation for the accumulation of stromal cells in persons with chronic inflammatory conditions such as RA lies in the possibility of blood-borne precursors. In the mid 1990s it was shown that vascular precursors (angioblasts) circulate in the blood of healthy people and that they could be recruited to sites of vasculogenesis in a rabbit ischemic hind limb model.[17] This finding demonstrated that circulating mesenchymal precursors exist outside the hemopoietic system. Subsequent work has confirmed the presence of circulating cells of a mesenchymal phenotype in human subjects. These cells bear a remarkable resemblance to the synovial fibroblasts found in the joints of persons with RA, which accumulate in large quantities in the joint lining despite little evidence of proliferation. Interestingly, Marinova-Mutafchieva and colleagues[18] showed that an influx of such cells preceded inflammation in a mouse collagen-induced arthritis model, suggesting that a role may exist for blood-borne stromal cell precursors in the initiation of inflammatory diseases. Furthermore, synovial fibroblasts themselves may migrate in the bloodstream, at least between distant sections of human cartilage in severe combined immunodeficiency (SCID) mice,[19] raising an intriguing parallel to cancer and the radical concept of RA as a metastatic disease of the stroma.

Another circulating precursor cell that could account for the accumulation of fibroblasts in disease is the fibrocyte. Fibrocytes constitute 0.1% to 0.5% of nonerythrocytic cells in peripheral blood and rapidly enter sites of tissue injury and contribute to tissue remodeling in models of inflammatory lung disease.[20] Fibrocytes are adherent cells with a spindle-shaped structure. They express class II major histocompatibility complex (MHC) and type I collagen and arise from within the $CD14^+$ (monocyte) fraction of peripheral blood.[21] They are capable of matrix elaboration and differentiate along fibroblast lineages under the influence of cytokines, particularly transforming growth factor (TGF)-β. The mere fact that a cell type apparently arising from within the monocyte lineage may become a "mesenchymal" stromal cell such as a fibroblast implies a further degree of plasticity and blurring of the apparently clear dividing line that was previously thought to exist between hemopoietic and nonhemopoietic lineages.

### Fibroblasts versus Mesenchymal Progenitor Cells

The potential role of circulating mesenchymal cell precursors (variously termed *mesenchymal stem cells* [MSCs], *mesenchymal stromal cells*, or *mesenchymal progenitor cells* [MPCs]) as sources of tissue fibroblasts is highlighted by the remarkable capacity of these cells to differentiate into other members of the connective tissue family, including cartilage, bone, adipocyte, and smooth muscle cells. This ability was initially demonstrated in bone marrow stromal cells, RA synovial fibroblasts, and circulating mesenchymal cells. Therefore, a characteristic mesenchymal phenotype could be defined on the basis of the hypothesis that the rheumatoid synovium becomes populated by a large proportion of circulating mesenchymal progenitor cells exported from the bone marrow. However, the property of trilineage differentiation ("pluripotentiality") has now been shown to be a property of many adult tissue fibroblasts, although varying somewhat between fibroblasts from different tissues, implying a hitherto unsuspected degree of plasticity in the body's stromal cell populations.[22] The two previously separate fields of mesenchymal precursor cell biology and largely disease-centered fibroblast biology have therefore rapidly converged. However, the concept of bone marrow stromal precursors remains interesting; in chimeric murine models with bone marrow Green fluorescent protein (GFP) expression, arthritic joints contained significantly more $GFP^+$ cells than did nonarthritic joints, supporting a bone marrow origin for expanded fibroblast populations.[23]

## PHYSIOLOGIC CHARACTERISTICS AND FUNCTIONS OF FIBROBLASTS

### Production of ECM Components

Ensuring ECM homeostasis is one of the primary functions of fibroblasts. To perform this function, fibroblasts must be able to produce and degrade ECM, as well as adhere to and interact with existing matrix components. Fibroblasts produce a number of ECM molecules—both fibrous proteins and polysaccharide gel components such as collagens, fibronectins, vitronectin, and proteoglycans—which are then assembled into a three-dimensional network. This mechanism provides a framework through which other cell types, which use varying strategies to navigate through the ECM, can move.[24] It also provides a substrate for the deposition of haptotactic (tissue rather than fluid-based) gradients of chemokines and stores of growth factors to direct cellular movement and behavior in a regional fashion.[25] The types of ECM molecules produced by individual populations of fibroblasts differ from tissue to tissue, reflecting the diversity of fibroblasts in different organs. For example, dermal fibroblasts produce significant amounts of type VII collagen, which adheres to the epidermal and dermal layers in the skin. Fibroblasts in other organs such as the lung and kidney produce mainly interstitial, fibrillar collagens (particularly types I and III).

In the synovial membrane, fibroblasts also have a barrier function, in that they provide the joint cavity and the adjacent cartilage with lubricating molecules such as hyaluronic acid, along with plasma-derived nutrients. Anatomically, the intimal synovial membrane is an unusual structure in that barrier function is maintained in the absence of a laminin-rich basement membrane, as occurs in epithelial structures. In addition to lacking a basement membrane, cellular contacts between the fibroblast-like synoviocytes also lack tight junctions and desmosomes. However, strong homophilic adhesion between synoviocytes is mediated by the adhesion molecule cadherin-11 (see later discussion), which is largely responsible for fibroblast organization into synovial tissue. In the presence of disease, fibroblasts must migrate to sites of tissue injury or remodeling and interact with ECM molecules through specific surface receptors. Through such receptors, fibroblasts must sense changes in both the structure and the cellular composition of connective tissues. They respond dynamically by adjusting the production of ECM components and cross-linking them into the appropriate matrix.

**TABLE 14-2** Fibroblast Cell Adhesion Molecules and Their Receptor/Ligand Molecules

| Family | CAM | Alternative Names | Ligands |
|---|---|---|---|
| Integrins | $\alpha_1\ \beta_1$ | VLA-1 | Laminin, collagen |
| | $\alpha_2\ \beta_1$ | VLA-2 | Laminin, collagen |
| | $\alpha_3\ \beta_1$ | VLA-3 | Laminin, collagen, fibronectin |
| | $\alpha_4\ \beta_1$ | VLA-4, CD49d/CD29 | VCAM-1, CS1 fibronectin |
| | $\alpha_5\ \beta_1$ | VLA-5 | Fibronectin |
| | $\alpha_6\ \beta_1$ | VLA-6 | Laminin |
| | $\alpha_L\ \beta_2$ | LFA-1, CD11a/CD18 | ICAM-1, ICAM-2, ICAM-3, JAM-A |
| | $\alpha_M\ \beta_2$ | Mac-1, CR3, CD11b/CD18 | ICAM-2, iC3b, fibrinogen, factor X |
| | $\alpha_X\ \beta_2$ | P150, 95, CD11c/CD18 | iC3b, fibrinogen |
| | $\alpha_E\ \beta_2$ | | E-cadherin |
| | $\alpha_4\ \beta_7$ | CD49d | Fibronectin, VCAM-1, MadCAM-1 |
| | $\alpha_v\ \beta_3$ | CD52/CD61, vitronectin receptor | Vitronectin, fibronectin, osteopontin, thrombospondin-1, tenascin |
| Ig superfamily | ICAM-1 | CD54 | LFA-1, Mac-1 |
| | ICAM-2 | | LFA-1 |
| | ICAM-3 | | LFA-1 |
| | VCAM-1 | | $\alpha_4\ \beta_1$, $\alpha_4\ \beta_7$ |
| | MadCAM-1 | | $\alpha_4\ \beta_7$, L-selectin |
| Cadherins | E-cadherin | Cadherin-1 | E-cadherin |
| | N-cadherin | Cadherin-2 | N-cadherin |
| | Cadherin-11 | OB-cadherin | Cadherin-11 |

ICAM, Intercellular adhesion molecule; Ig, immunoglobulin; JAM, junctional adhesion molecule; LFA, lymphocyte function–associated antigen; Mac-1, macrophage 1 antigen; MAdCAM, mucosal addressin cell adhesion molecule; OB-cadherin, osteoblast cadherin; VCAM, vascular cell adhesion molecule; VLA, very late antigen.

## Attachment to and Interaction with Extra-cellular Matrix

### Integrins

Integrins are key mediators of both cell-to-matrix and cell-to-cell adhesive interactions. They are expressed as transmembrane heterodimers containing one α- and one β-subunit, of which at least 25 αβ combinations are known (Table 14-2). The main adhesion molecules responsible for the attachment of fibroblasts to collagen are $\alpha_1\beta_1$ and $\alpha_2\beta$ integrins, whereas other $\beta_1$ integrins such as $\alpha_4\beta_1$ and $\alpha_5\beta_1$ integrins mediate attachment of fibroblasts to fibronectin and its spliced variants. In addition, $\alpha_v$ integrins are responsible for attachment to vitronectin.

### Syndecans

In addition to conventional integrin-to-ligand binding, additional accessory molecules allow for the integration of adhesive contacts and local growth factor signaling. Syndecans are a family of four single transmembrane domain proteins that carry three to five heparan sulfate and chondroitin sulfate chains, allowing for interaction with a large variety of ligands including fibroblast growth factors, vascular endothelial growth factor (VEGF), TGF-β, and ECM molecules such as fibronectin.[26] Syndecans are expressed on fibroblasts in a tissue-specific and development-dependent manner. Data from syndecan knockout mice indicate that syndecan-4 is involved in wound healing and that the response of syndecan-4–deficient fibroblasts to fibronectin attachment is significantly altered.[27]

### Immunoglobulin Superfamily Receptors

The immunoglobulin (Ig) superfamily is a diverse group of transmembrane glycoproteins defined by the presence of one or more Ig-like repeats of 60 to 100 amino acids with a single disulfide bond.[28] Although it includes numerous adaptive immune system genes (e.g., Igs, T cell receptor, and MHC), adhesion proteins such as intercellular adhesion molecules (ICAMs) 1 to 3, vascular cell adhesion molecule-1 (VCAM-1), and mucosal addressin cell adhesion molecule (MAdCAM) mediate both cell-to-cell interactions and adhesive interactions with integrins (see Table 14-2).

### Cadherins

Cadherins mediate homotypic, calcium-dependent adhesive interactions with the same cadherin species expressed by neighboring cells.[29] Classical cadherins possess five extracellular domains, a single-pass transmembrane domain, and a highly conserved cytoplasmic tail. The cytoplasmic tail interacts with β-catenin, which in turn binds α-catenin, forming a linkage between the cadherin-catenin complex and the actin cytoskeleton. Tightly regulated expression of cadherins is essential to embryogenesis but is also critical for tissue morphogenesis and tissue-specific cell differentiation. Cadherins also modulate cell proliferation and invasion through activation of intra-cellular signal transduction pathways, modulation of MMP production, and association with growth factor receptors.[30-32]

### Adhesion Molecule-Mediated Signaling

Importantly, interaction with adhesion molecules not only regulates adhesion and motility but also directly influences activation status, apoptosis, and pro-inflammatory and anti-inflammatory responses in fibroblasts and other cells. The engagement of cell adhesion molecules such as integrin receptors on the surface of fibroblasts results in the formation of focal adhesion complexes, which activate intracellular signaling cascades that regulate cell proliferation

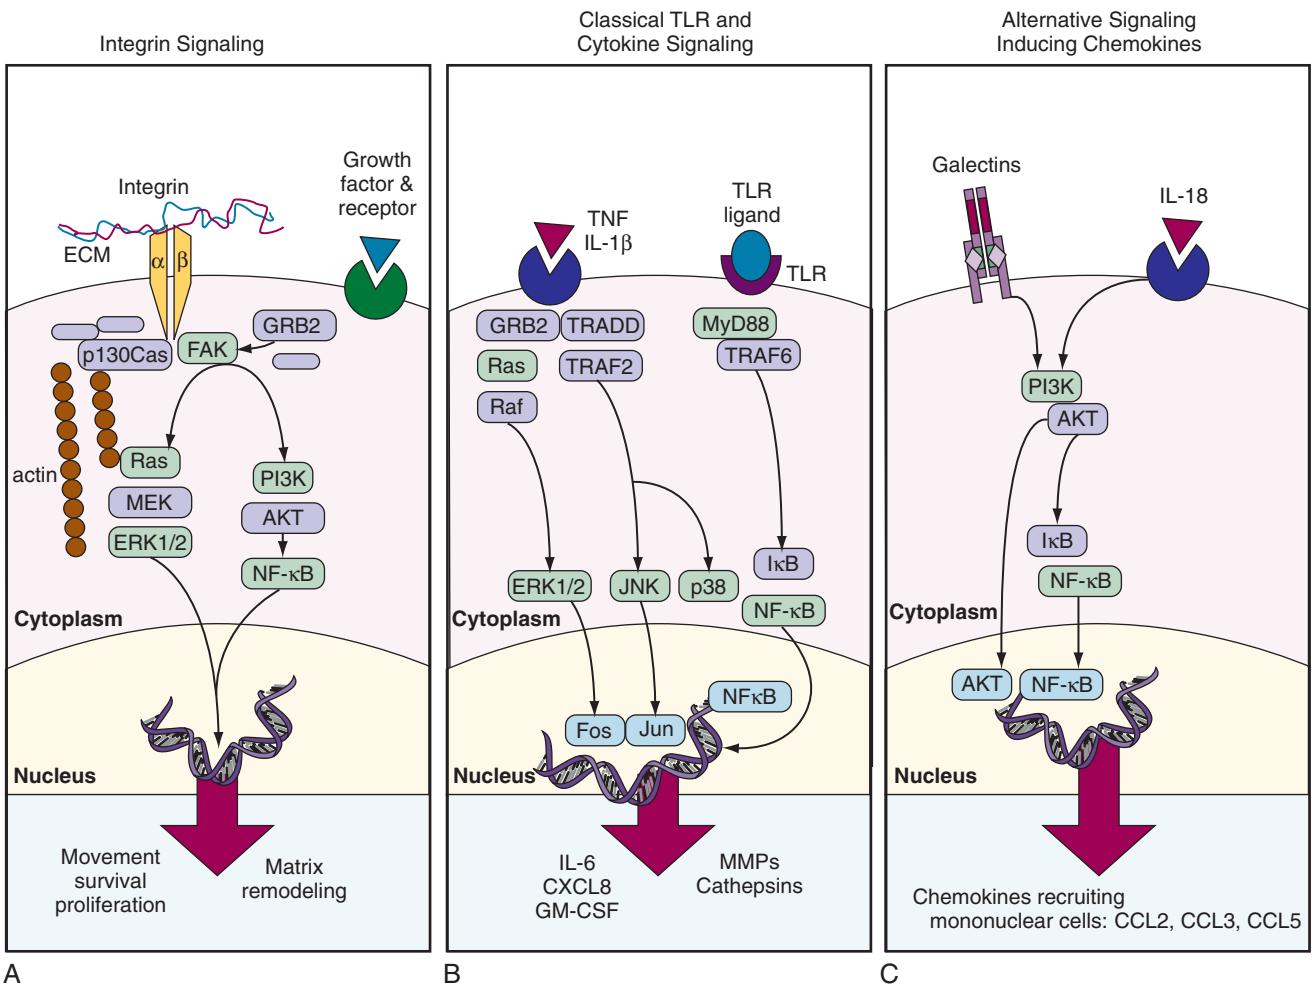

**Figure 14-3** Important signaling pathways in synovial fibroblasts. **A,** Integrin signaling in fibroblasts. The engagement of integrins and extra-cellular matrix (ECM)–bound growth factors on the cell surface of fibroblasts results in the initiation of signaling cascades that result in changes in (1) cell motility through reorganization of the cytoskeleton, (2) cell survival (e.g., through activation of the Akt-NF-κB pathway), and (3) the production of matrix molecules, matrix-degrading enzymes, and soluble mediators through the activation of mitogen-activated protein kinases (MAPK). **B,** The three MAPK pathways are also pivotal in pro-inflammatory cytokine activation of synovial fibroblasts, with tumor necrosis factor (TNF), interleukin (IL)-1β, and IL-6 all capable of activating the three main pathways. In particular, c-Jun N-terminal kinase (JNK) and p38 MAPK pathways are crucial to the production of matrix metalloproteinases (MMPs) such as the collagenases. Fos family members and jun dimerize to form the activator protein-1 (AP-1) transcription factor for which binding sites are present on multiple pro-inflammatory genes, including the MMPs. **C,** There is evidence for a discrete pro-inflammatory pathway for some ligands, which might bypass the classical MAPK and nuclear factor-κB (NF-κB)/AP-1 pathways, signaling via phosphatidylinositol 3-kinase (PI3K) to elicit secretion of chemokines. The chemokines specifically recruit the mononuclear cell population, which predominates in persistent inflammatory disease. GM-CSF, Granulocyte-macrophage colony-stimulating factor; TLR, Toll-like receptor.

and survival, the secretion of certain cytokines and chemokines, and matrix deposition and resorption. In particular, integrin-to-fibronectin engagement induces MMP expression, linking adhesion-to-matrix remodeling[33] (Figure 14-3). Among the signaling molecules that transmit signals from the integrins to the cell interior, focal adhesion kinase (FAK) plays a central role.[34] FAK, a tyrosine kinase, is recruited into newly established focal contacts and, in turn, recruits other adapter proteins such as p130Cas and Grb2. This process leads to phosphatidylinositide 3-kinase (PI3K) and Src-kinase activation and promotes the initiation of a variety of signaling cascades, culminating in phosphorylation of the extra-cellular regulating kinase (ERK) mitogen-activated protein kinases (MAPKs) and activation of transcription factors. Such pathways can also be activated through FAK-independent signaling events, such as through growth factor receptor ligation. The exact mechanisms by which different signals cooperate to mediate a specific response of fibroblasts and how this translates into distinct diseases are not yet fully defined.

## Degradation of Extra-cellular Matrix by Fibroblasts

Remodeling of the ECM requires fibroblasts to express an extensive repertoire of matrix-degrading enzymes

with varying specificity. Although these matrix-degrading enzymes are crucial to tissue maintenance and repair, inappropriate overexpression of such enzymes is a key factor in the joint damage, particularly to cartilage, that occurs in inflammatory disease. Such enzymes fall into a number of families, including MMPs, tissue inhibitors of metalloproteinases (TIMPs), cathepsins, and aggrecanases, which are covered in detail in Chapter 8.

With the exception of MMP-2 and the membrane-type (MT)-MMPs, which are constitutively expressed by fibroblasts, MMP expression is regulated by extra-cellular signals via transcriptional activation in fibroblasts. Three major groups of inducers can be differentiated: pro-inflammatory cytokines, growth factors, and matrix molecules. Among the cytokines, IL-1 is perhaps the most potent inducer of a variety of MMPs, including MMP-1, MMP-3, MMP-8, MMP-13, and MMP-14. Fibroblast growth factor (FGF) and platelet-derived growth factor (PDGF) are also known inducers of MMPs in fibroblasts because they potentiate the effect of IL-1 on MMP expression. All MMP promoter regions except MMP-2 contain activator protein-1 (AP-1) binding sites; however, there is good evidence that all MAPK families (ERK, c-Jun N-terminal kinase [JNK], and p38 pathways; see Figure 14-3), in addition to activators of nuclear factor-κB (NF-κB), signal transducer and activator of transcription (STAT), and ETS transcription factors participate in MMP regulation.[35-39] Matrix proteins (i.e., collagen and fibronectin), and especially their degradation products, also activate MMP expression in fibroblasts, providing the possibility for site-specific MMP activation in regions of matrix breakdown.[40]

## Fibroblasts as Innate Immune Sentinels

Classically, macrophages have been studied as sources of inflammatory cytokines and chemokines in response to innate immune stimuli and portrayed as immune sentinel cells accordingly. However, when activated by substances released during tissue injury or the products of invading microorganisms, fibroblasts are capable of elaborating a broad repertoire of inflammatory mediators, which fully justifies their classification as immune sentinel cells. Through expression of TLRs 2, 3, and 4, fibroblasts respond to bacterial products such as lipopolysaccharide (LPS) by activating the classical NF-κB and AP-1 inflammatory pathways, generating chemokines capable of recruiting inflammatory cells, and generating metalloproteinases capable of degrading matrix.[41-43] However, TLR expression may be increased by pro-inflammatory cytokines TNF and IL-1β within the local microenvironment[44] and may also be activated by endogenous cellular debris such as necrotic cells in synovial fluid, leading to widespread fibroblast activation in disease.[45] As immune sentinels, fibroblasts are able to bridge the innate and adaptive immune responses through expression of the molecule CD40. This molecule was initially assumed to be restricted in its expression to antigen-presenting cells such as macrophages and DCs. However, it is widely expressed by fibroblasts within discrete tissues. CD40 engagement by its ligand CD40L expressed on a restricted population of immune cells including activated T lymphocytes, is critical for the further induction of pro-inflammatory cytokines and chemokines during an immune response, as well as for antibody production by CD40-expressing B lymphocytes.

Fibroblasts also need to be able to respond to more generic danger signals. The intra-cellular apparatus for response to danger signals such as high levels of urate has recently been identified as the nucleotide-binding oligomerization domain (NOD)-like receptor family, which is made up of NOD and NALP (i.e., NACHT domain, leucine-rich repeat [LRR] domain, and pyrin domain [PYD]-containing protein) receptors. A high local level of urate released by dying cells triggers formation of the active NALP3 inflammasome complex, which results in release of IL-1.[46]

Expression of high levels of NOD-1, NOD-2, and NALP3 (cryopyrin) are seen in the RA synovium and can be induced in fibroblasts by TLR ligands and/or TNF. Furthermore, synergy between TLR and NOD stimulation, with increased IL-6 production in response to NOD-1, TLR2, and TLR4 ligands, has recently been demonstrated. The cytokine IL-17 also regulates multiple TLRs in RA synovial fibroblasts.

## Role of Specialized Fibroblast Subsets within Tissue Microenvironments

Combining surface markers with consistent function has been the key to decades of development in the field of leukocyte biology. By comparison, stromal cell biologists have had remarkably few such stable markers. However, this situation is now gradually changing, and certain areas of developmental biology have spearheaded identification of putative markers (such as CD248) through approaches such as immunization of animals with human fibroblasts and digesting and identifying stromal cell subpopulations in tractable organ systems. One example is the murine thymic stroma, in which subsets with both geographic and functional consistency have been identified. For instance, Link and colleagues identified $CD45^{-}$, $gp38^{+}$ stromal cells in the thymus as T-zone fibroblastic reticular cells.[47] This population of cells, which is geographically restricted to the T zone, provides a limited pool of essential homeostatic survival factors, IL-7 and CCL19, for T lymphocytes, serving a key niche function for which adaptive immune cells must compete.[47] Also, gp38 marks populations of fibroblastic reticular cells within the lymph node that modulate trafficking of DCs.[48]

A further subpopulation of specialized fibroblast-like cells of mesenchymal origin is the pericyte. These cells ensheath small blood vessels (i.e., arterioles, capillaries, and venules) and are involved in vasculogenesis, matrix stabilization, and immunologic defense. Pericytes have been hypothesized to represent the extralymphoid source of mesenchymal progenitor cells and express markers consistent with mesenchymal stem cells. Their further definition with newer stromal cell markers such as CD248 and CD146 will be able to establish a mesenchymal progenitor cell niche.[49]

## Fibroblast-like Synoviocytes in the Normal Synovium

The normal synovium provides an excellent prototypic model of fibroblast subsets defined by known markers, some of which are responsive to disease. In healthy people the

synovium is a delicate, thin, two-layer structure attaching bone and the joint capsule. One layer, a two- to three-cell-thick lining layer, is formed in roughly equal proportions of $CD68^+$, phagocytic type A macrophage-like synoviocytes, and type B mesenchymal, fibroblast-like synoviocytes (FLS). This layer serves a barrier function, and FLS secretes lubricative substances, including hyaluronic acid and lubricin, along with secreting the lining layer matrix. The second layer is the sublining layer, which is composed of less densely packed fibroblasts and macrophages in a loose tissue matrix along with blood vessel networks. FLS in the lining layer are associated with a number of cellular markers (see Table 14-1), including CD55 (decay accelerating factor [DAF]), VCAM-1 (which, outside of T cell–to-integrin interactions, is generally only expressed by bone marrow fibroblasts providing support for the B cell developmental niche[50]), uridine diphosphoglucose dehydrogenase (UDPGD), reflecting the ability to synthesize hyaluronan, and the novel marker gp38.[51] Sublining FLS are instead marked by the nonspecific cellular marker CD90 (Thy-1), which also recognizes endothelium, and by the recently discovered marker CD248, which marks both pericytes and stromal fibroblasts. Gp38 marks cells in the sublining region, including lymphatic endothelium and pericytes (Figure 14-4).

As mentioned earlier, the unique lining layer barrier function is not supported by a basement membrane and conventional tight junctions but instead by homotypic interactions between cadherin-11 molecules.[52] Randomly assorted cells expressing classical cadherins such as cadherin-11 will sort themselves in a cadherin-specific manner, emphasizing their importance in the generation and maintenance of organ integrity. Cadherin-11 mediates selective association of mesenchymal rather than epithelial tissues, a function that is carried forward after embryogenesis in structures such as the joint, lung, and testis.[53] Cadherin-11 knockout mice exhibit a hypoplastic synovial lining that lacks the normal numbers of synovial lining cells and is deficient in ECM quantity.[54] Adhesion between type A and type B synoviocytes is maintained by ICAM-1:$\beta_2$ integrin and VCAM-1:$\alpha_4\beta_1$ integrin interactions.

By virtue of their role in defining the geography of specialized tissues, fibroblasts and other stromal cells exist in living organisms within three-dimensional environments, whereas the vast majority of experiments performed using fibroblasts in the laboratory are still conducted within two-dimensional environments. Furthermore, fibroblasts are frequently grown in nonphysiologic stimuli such as serum, to which fibroblasts would not normally be exposed unless tissue damage were to occur. Behavior is significantly different when cells are cultured in artificial three-dimensional environments.[55] It is therefore all the more remarkable that fibroblasts cultured using conventional two-dimensional

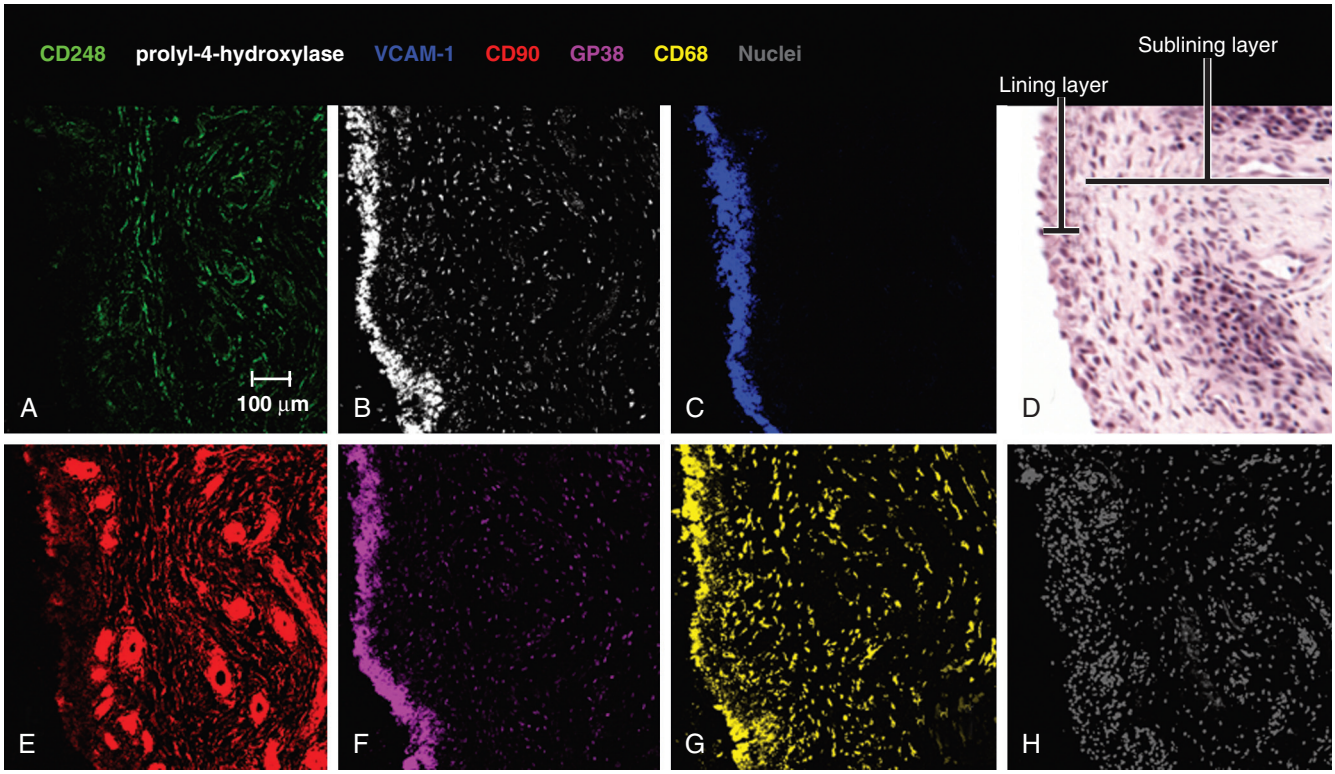

**Figure 14-4** Microscopic appearance of the synovium and stromal cell markers. The microscopic structure of hematoxylin and eosin–stained synovium is illustrated in **D,** indicating lining and sublining layers. This geographic structure is reflected in serial frozen sections of rheumatoid arthritis synovium stained for stromal markers **(A-C, E-G).** For reference, a nuclear stain is shown in **H. A,** CD248 stains only sublining fibroblasts. **B,** Prolyl-4-hydroxylase stains most populations of synovial fibroblasts. **C,** Vascular cell adhesion molecule-1 (VCAM-1) (CD106) characteristically stains only the lining layer. **E,** CD90 (Thy-1) stains predominantly sublining layers but also strongly stains endothelial cells, outlining synovial vasculature. **F,** gp38 marks lining layer cells and a proportion of sublining cells. **G,** CD68 highlights macrophage-like synovial cells in the lining layer and resident tissue macrophages in the sublining layer.

techniques retain characteristics such as positional memory and unique cytokine profiles.

Recent work has addressed the issue of three-dimensional synovial models. In so-called "micromass cultures," FLS, but not dermal fibroblasts, within laminin-containing spheres reproduced a lining layer structure with production of lubricin, support for co-cultured monocytic cells, and expansion of the membrane upon stimulation with pro-inflammatory stimuli such as TNF. Some cells also remained in a "sublining" zone of low density.[56] FLS therefore have the ability to self-organize in a tissue organoid, which recapitulates some of the key features of the synovium. This finding is further evidence of the robustness of epigenetic programming, which determines site and organ specialization.

## FIBROBLASTS IN RHEUMATIC DISEASES

### Role of Fibroblasts in Persistent Inflammation

Inflammatory reactions proceed against the backdrop of specialized stromal microenvironments. The response to tissue damage involves a carefully choreographed series of interactions among diverse cellular, humoral, and connective tissue elements. In order for an inflammatory lesion to resolve, dead or redundant cells that were recruited and expanded during the active phases of the response must be removed. In addition, resident fibroblasts attempt to repair damaged tissue.

It is becoming increasingly clear that fibroblasts are not only passive players in immune responses but also actively determine the switches that govern progression from acute to chronic inflammation, as well as those governing resolution or the progression to chronic, persistent inflammation. The "switch to resolution" is an important signal that permits tissue repair to take place and enables immune cells to return to draining lymphoid tissues (lymph nodes) in order for immunologic memory to become established. However, in chronic immune-mediated inflammatory diseases such as RA, fibroblasts contribute to the inappropriate recruitment and retention of leukocytes in a site- or organ-dependent manner, leading to tissue- and site-specific initiation and subsequent relapse of chronic persistent inflammatory disease, effectively a "switch to persistence."[57]

It is now recognized that fibroblasts themselves may undergo fundamental changes while responding to such environmental stimuli. It is known that during wound healing and under profibrotic conditions, some fibroblast-like cells are transformed into myofibroblasts, which are distinct from tissue fibroblasts in terms of both their phenotype and their behavior.[58] The mechanisms underlying such persistent phenotypic change, which is maintained through cellular generations, are highly likely to involve epigenetic modifications of gene promoters and their closely related histones (see Chapter 22). This has been shown recently in both human and murine renal fibrotic disease, where hypermethylation of the promoter region of a ras oncogene inhibitor led to gene silencing, ras pathway activation, and hence persistent fibrogenesis.[59] Such fibrotic transformation of fibroblasts is also characteristic of systemic sclerosis, a generalized fibrotic disorder that affects the skin and various internal organs such as the lungs, heart, and gastrointestinal tract (see Chapter 84). The overproduction of ECM components, particularly type I, III, VI, and VII collagen, by skin fibroblasts is a hallmark of this disease and is closely linked to the disease-specific activation of these fibroblasts. This pattern of activation includes not only a distinct profile of ECM overproduction but also altered responses to both inflammatory mediators and immune cells.[60] Although the phenotype of fibroblasts in RA is not fundamentally profibrotic in this sense, the hallmark of these cells, both in vitro and in vivo, is also a persistently imprinted phenotype that is maintained even in the absence of continuous stimulation by inflammatory triggers or leukocytes.

## FIBROBLAST-LIKE SYNOVIOCYTES IN RHEUMATOID ARTHRITIS

In inflammatory arthritis such as RA, the two compartments of the synovium undergo radical change. The lining layer undergoes dramatic hyperplasia, sometimes reaching 10 to 20 cells in depth with both type A and type B cell populations expanded and becoming merged with the sublining. At the articular borders of the synovium, the thickened synovial lining layer may become a mass of "pannus" tissue rich in FLS and osteoclasts, which aggressively invade the adjacent articular cartilage and subchondral bone, respectively. The sublining layer also undergoes expansion, with sometimes huge infiltrates of inflammatory cells including macrophages, mast cells, T cells, B cells, and plasma cells in addition to DCs. T and B lineage cells may remain in diffuse infiltrates or may coalesce into aggregates of cells varying from simple perivascular "cuffs" a few cells in diameter to structures resembling B cell follicles in up to 20% of samples.[61] This increased activity is supported by further ECM production and neoangiogenesis, although the inflamed synovium remains in a state of relative hypoxia.[62]

As mentioned previously, cadherin-11 serves a vital role in preserving the integrity of the synovial lining layer, and cadherin-11 knockout mice display a hypoplastic lining layer. However, when cadherin-11 knockout mice are evaluated in the K/BxN serum transfer model, invasiveness is reduced with a 50% reduction in inflammation. Similarly, cultured fibroblasts with mutant cadherin-11 constructs also demonstrate impaired invasiveness into cartilage.[54,63] Cadherin-11 expression is also much higher in RA than in osteoarthritis (OA) or normal synovium. This unique structural molecule may therefore emerge as a therapeutic target[54]; because of shared roles in invasive disease, targeting of this molecule in breast cancer is currently in development.[64]

### Persistent Activated Fibroblast Phenotype in the Rheumatoid Arthritis Synovium

Increased expression of cadherin-11 is but one facet of the persistent, activated phenotype of rheumatoid FLS, which remains stable even after culturing in vitro for many months. These cells play a direct role in tissue damage through secretion of multiple MMPs and cathepsins, which degrade cartilage and bone tissues in the joint. In vitro functional assays such as the laminin invasion assay produce intriguing results, in which the degree of invasion with a given in vitro cultured fibroblast sample correlates with the degree of radiographic progression seen in the joints of the patient

from whose samples the fibroblasts were initially cultured.[65] The most compelling evidence for a persistent phenotype is the attachment to and invasion of fibronectin-rich matrix such as human cartilage in the absence of functioning leukocyte immune cells in the SCID mouse model of arthritis.[66] Here, fibroblasts in a tissue construct with human cartilage are implanted under the kidney capsule or skin of immune-incompetent SCID or $Rag^{-/-}$ mice. Multiple-passage cultured rheumatoid FLS, but not OA or normal FLS, invade and destroy the co-implanted human cartilage. This model has been used to explore the in vivo mechanisms governing invasiveness. For example, targeting MMP-1 and cathepsin L using ribozymes inhibits cartilage destruction.[67,68] The effectiveness of glucocorticoids and the relative efficacy of different formulations of methotrexate in preventing erosions have also been examined.[69,70]

Unbiased approaches to determining the key regulators of fibroblast invasiveness have made rapid recent progress. Transcriptomic approaches linking gene expression in RA fibroblasts and macrophages have revealed invasiveness pathways within fibroblasts regulated by complementary macrophage inflammatory pathways that are strongly driven by IL-1β stimulation. Key genes include periostin osteoblast-specific factor (POSTN) and twist basic helix–loop–helix transcription factor 1 (TWIST1).[71,72] The impact of TNF and IL-17 stimulation on the transcriptome of RA fibroblasts has been examined, revealing critical hypoxia regulated genes linked to invasiveness, including MMP-2 and the chemokine receptor CXCR4, which is already implicated in disease persistence.[73]

An alternative unbiased approach to dissecting function involves the parallel study of cellular enzymes mediating tyrosine phosphorylation of key signaling molecules (protein tyrosine phosphatases [PTPs]). Investigation of the PTPome of synovial fibroblasts in RA compared with OA revealed a dual role for SH2 domain–containing phosphatase 2 (SHP2); knockdown of this enzyme reduced both invasiveness and survival of RA FLS, suggesting a pivotal signaling molecule.[72]

Fibroblasts implanted with cartilage migrate to a contralateral cell-free implant and that subcutaneous, intraperitoneal, and intravenously injected fibroblasts will also migrate to sections of human cartilage, suggesting a tropism to damaged cartilage tissue. This important finding raises the question of which cell populations are grown from the synovium when tissue is digested and adherent cells are cultured in vitro: lining layer cells, sublining cells, or a mixture of both? From a methodologic perspective, answering this question is a challenge. However, we do know from transcriptomic approaches that the phenotype remains more stable in tissue culture than might be expected, with little transcriptional divergence over the first two to four passages and the level of differentially expressed genes between parallel cultures rising to greater than 10% only after passage 7.[74]

These models demonstrate the remarkably stable and disease-specific phenotype of cultured RA synovial fibroblasts, which includes high basal and stimulated expression of signature cytokines such as IL-6 and chemokines (discussed later).[75] RA synovial fibroblasts also express characteristic adhesion and immune-modulating molecules such as VCAM-1, galectin-3, and a specific repertoire of TLRs, which initiate innate immune cellular responses. A satisfactory molecular explanation for the stable phenotype of RA synovial fibroblasts has until recently evaded the field. However, epigenetic changes including DNA methylation; histone modifications such as acetylation, methylation, and citrullination; and altered micro RNA (miRNA) expression have now been suggested to underlie the observed persistent changes in fibroblast gene transcription and post-transcriptional repression (see Chapter 22). Further characteristic aspects of the RA FLS phenotype and their biology are discussed extensively in Chapter 69.

## Interactions of Fibroblasts with Leukocytes

### Recruitment of Inflammatory Infiltrates into the Joint

Stromal elements such as synovial fibroblasts are subject to a pro-inflammatory cytokine network within the inflamed synovium. Direct-contact interactions with other infiltrating cells such as T lymphocytes lead to high levels of expression of many inflammatory chemokines (see Figure 14-3). Neutrophil-attracting chemokines are expressed at high levels by stimulated fibroblasts and include CXCL8 (IL-8); CXCL5 (ENA-78); and CXCL1 (GRO-α).[76-78] Monocytes and T cells are recruited by a range of chemokines found at high levels in the synovium; CXCL10 (IP-10) and CXCL9 (Mig) are highly expressed in synovial tissue and fluid.[79] CXCL16 is also highly expressed in the RA synovium and acts as a potent chemoattractant for T cells.[80] CCL2 (MCP-1) is found in synovial fluid and is known to be produced by synovial fibroblasts; it is considered to be a pivotal chemokine for the recruitment of monocytes.[81] CCL3 (MIP-1α), CCL4 (MIP-1β), and CCL5 (RANTES) are chemotactic for monocytes and lymphocytes and are known products of synovial fibroblasts.[79,82] CCL20 (MIP-3α) is also overexpressed in the synovium and has a similar chemoattractant profile via its specific receptor, CCR6.[83] CX3CL1 (fractalkine) is also widely expressed in the rheumatoid synovium. A number of chemokine receptors have been shown to differ between peripheral blood and synovial leukocytes, suggesting that they are enriched in the synovium either though their selective recruitment by endothelial-expressed chemokines or after upregulation by the microenvironment after their recruitment.

### Fibroblast Support for Leukocyte Survival

Stromal cell support for the survival of leukocyte populations fulfills a physiologic role in certain organs within the body. The selective recruitment and support of hemopoietic subsets is an essential physiologic function of stromal cells in specific microenvironments. For instance, immature B lymphocytes are completely dependent on factors such as IL-6 produced by bone marrow stromal cells. Although the bone marrow niche plays a critical role in the early development of all hemopoietic leukocyte populations, it also acts as an active reservoir for terminally differentiated leukocyte subpopulations, including CD4 and CD8 T cells and neutrophils. The bone marrow stromal microenvironment therefore maintains not only the selective survival, differentiation, and proliferation of all lineages of immature hemopoietic cells but also, in some

cases, the survival of their mature counterparts. The stromal microenvironment plays a crucial role in the maintenance of such survival niches, which are not generic but are highly specific to certain organs and tissues, resulting in site-specific differences in the ability of different stromal cells to support the differential accumulation of leukocyte subsets.

In the case of an inflammatory response, successful resolution requires the removal of the vast majority of immune cells that were recruited and expanded during the active phase of the inflammation. A number of studies have shown that during the resolution phase of viral infections, the initial increase in T cell numbers in peripheral blood that is seen within the first few days is followed by a wave of apoptosis occurring in the activated T cells. This situation is mirrored within tissues, where apoptosis induced by the molecule Fas occurs at the peak of the inflammatory response and may be responsible for limiting the extent of the immune response. In contrast, the resolution phase appears to be principally triggered by cytokine-deprivation–induced apoptosis, during which leukocytes compete for a shrinking pool of survival factors provided by the microenvironment, leading to programmed death of those cells, which are surplus to requirements.

In RA the resolution phase of inflammation becomes disordered. Recent studies have shown that a failure of synovial T cells to undergo apoptosis contributes to the persistence of the inflammatory infiltrate. The T cell survival pathway shares all the essential hallmarks of a stromal cell, cytokine-mediated mechanism (high B cell lymphoma [Bcl]-$X_L$, low Bcl-2, and lack of cell proliferation). Type I IFNs (IFN-α and -β), which are produced by synovial fibroblasts and macrophages, have been identified as one of the principal factors responsible for prolonged T cell survival in the rheumatoid joint (Figure 14-5).[57] Interestingly, although type I IFN is beneficial in multiple sclerosis (a disease in which tissue scarring and low levels of T cell infiltrates are observed), these results suggest that type I IFN is not likely to be a successful therapy for persons with RA, a prediction that has been borne out in clinical trials.[84] It is likely that this mechanism of stromal cell–induced leukocyte survival occurs in many chronic inflammatory conditions in which T cells accumulate.

Not surprisingly, other leukocyte subpopulations have been shown to derive support from stromal cells. Although fibroblast support for T cell and B cell survival exhibits site-specific properties, neutrophil survival is dependent on prior cytokine activation of fibroblasts and shows no differences between fibroblasts taken from different anatomic sites.[75] Plasma cells are, of course, rescued from apoptosis within the bone marrow stem cell niche,[85] but mast cells of the gut are rescued by intestinal fibroblasts,[86] whereas dermal fibroblasts maintain Langerhans-like cells in the skin.[87] Fibroblast modulation of inflammatory and differentiation pathways in monocyte lineage cells has become a recent focus as the role of differentially polarized macrophage populations becomes more prominent. Recent transcriptomic analyses of co-cultured RA FLS and macrophages demonstrated not only that shared inflammatory pathways are present in both cell types but that co-cultured RA FLS modulate up to a third of TNF-regulated pathways in macrophages.[88]

### Fibroblast-Mediated Retention of Leukocytes in Tissue

Although inhibition of T cell death by stromal cells at sites of chronic inflammation contributes to T cell accumulation, it is unlikely to be the only mechanism because lymphocytes should be able to leave the inflamed tissue during the resolution of inflammation, even if their death is inhibited. A number of studies have recently reported that the synovial microenvironment contributes directly to the inappropriate retention of T cells within the joint by an active chemokine-dependent process. The presence of high levels of inflammatory chemokines, produced by stromal cells, is a characteristic of environments such as the rheumatoid synovium. However, recent data suggest that, paradoxically, constitutive chemokines, which are involved in the recruitment of lymphocytes to secondary lymphoid tissues, are ectopically expressed in immune-mediated inflammatory diseases. The constitutive chemokine CXCL12 (SDF-1) and its receptor CXCR4 emerged as unexpected but crucial players in the accumulation of T lymphocytes within the rheumatoid synovial microenvironment. This chemokine-receptor pair plays an important role, both in the constitutive traffic of lymphocytes and in the recruitment and retention of hemopoietic cells within the bone marrow. Unexpectedly, $CD45RO^+$ T lymphocytes in the rheumatoid synovium were found to express CXCR4 receptors at high levels in the rheumatoid synovium. The CXCR4 ligand CXCL12 was highly expressed on endothelial cells at the sites of T cell accumulation.[89,90] In addition, stromal cell–derived TGF-β is responsible for upregulation of CXCR4 receptors on T cells in the synovium.[89] Evidence also suggests that the stability of lymphocyte infiltrates is reinforced by a positive feedback loop whereby tissue CXCL12 promotes CD40 ligand expression on T cells, which in turn stimulates further CXCL12 production by CD40-expressing synovial fibroblasts. Furthermore, levels of CXCL12 secreted by synovial fibroblasts are controlled in part by T cell–derived IL-17.[91]

Therefore, clear evidence supports the hypothesis that aberrant ectopic constitutive expression of chemokines such as CXCL12, CCL19, and CCL21 by synovial stromal cells contributes to the retention of T cells within the RA synovium.

Other cell constituents of the rheumatoid inflammatory infiltrate may be affected by the CXCL12/CXCR4 axis. Blades and colleagues[92] have shown increased expression of CXCL12/CXCR4 by monocyte/macrophage cells in RA compared with OA. In addition, using implanted human synovial tissue in SCID mice, they demonstrated that monocytes are recruited into transplanted synovial tissue by CXCL12.[92] Contact-mediated B cell survival induced by synovial fibroblasts has also been shown to depend on CXCL12, B cell activating factor (BAFF)/BLyS, and CD106 (VCAM-1)–dependent mechanisms that are independent of TNF.[50,93] Overexpression of CXCL12 has also been identified as a distinct feature of RA, as opposed to OA synovia, using complementary DNA arrays. Data validating these findings in vivo have come from a collagen-induced arthritis model of RA in DBA/1 IFN-γ receptor deficient-mice, where administration of the specific CXCR4 antagonist AMD3100 significantly ameliorated disease severity.[94] In another murine collagen-induced arthritis model, the small

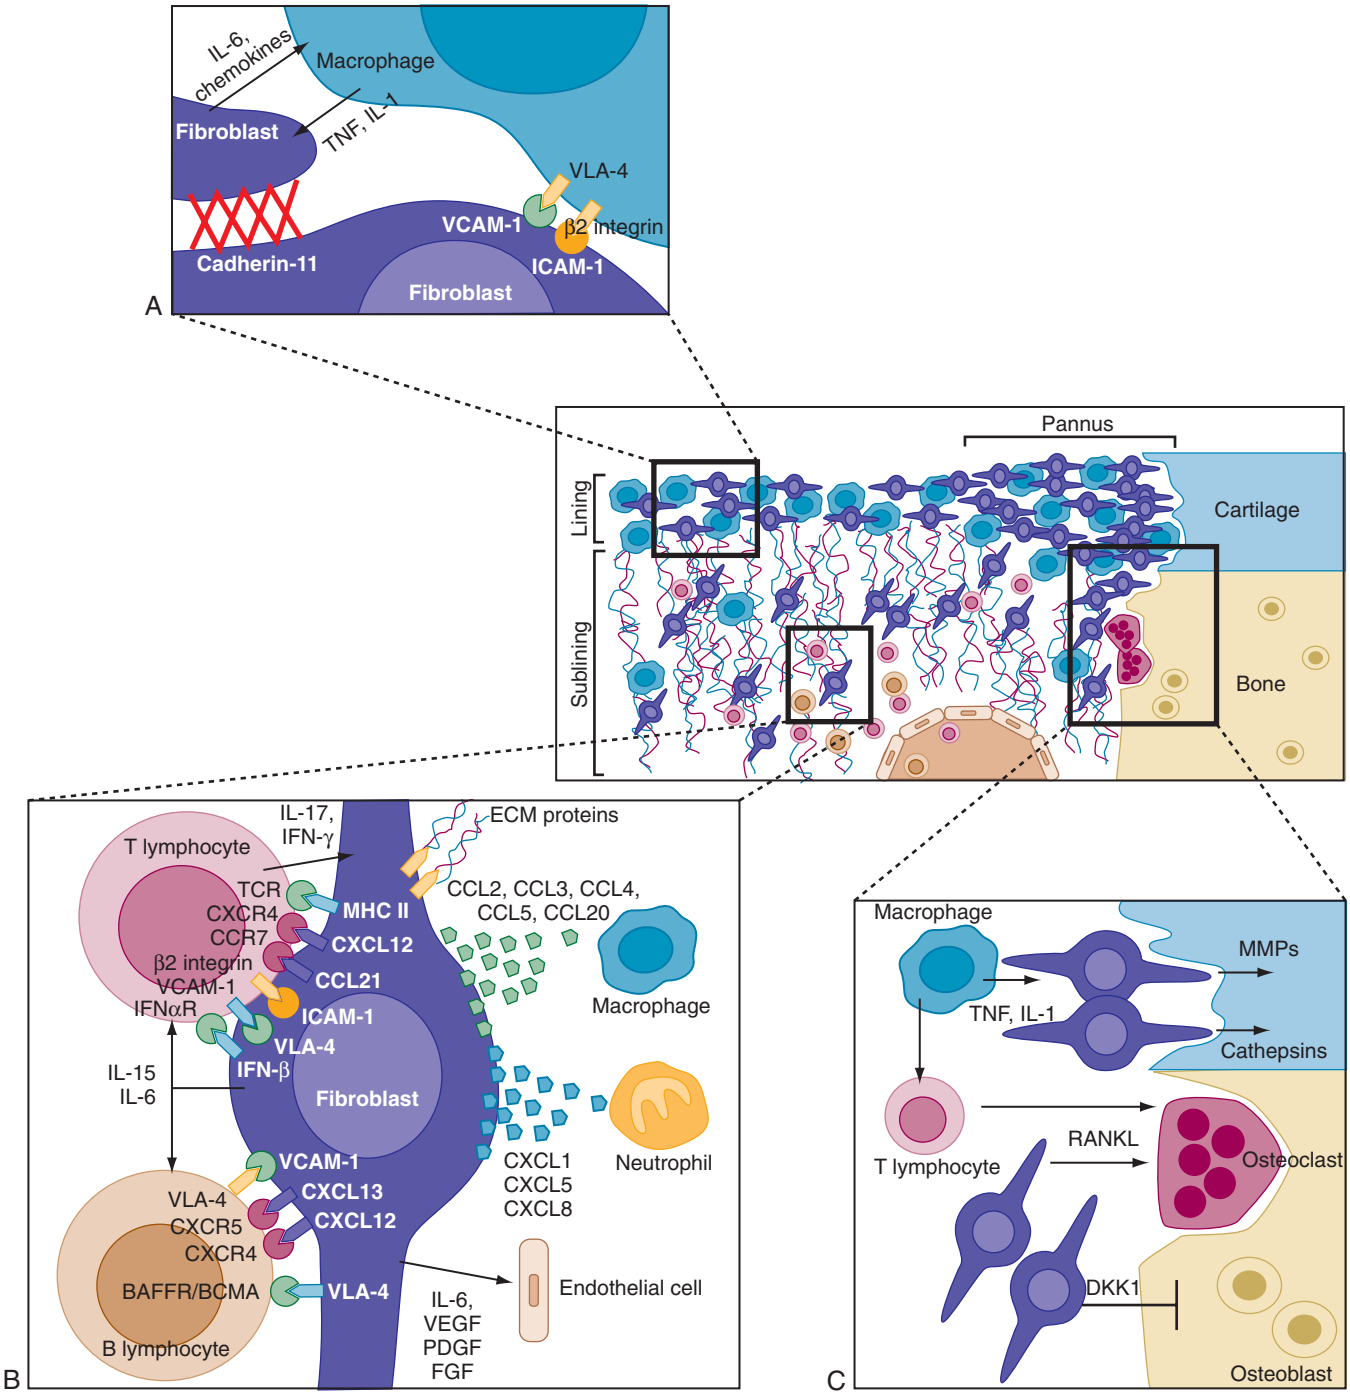

**Figure 14-5** Cell-cell interactions in the synovium. Synovial fibroblasts interact with multiple cell types in the rheumatoid arthritis (RA) synovium to maintain persistence of inflammation and continued joint destruction. **A,** Fibroblast-like synoviocytes in the RA synovial lining interact with macrophage-like synoviocytes through both secretion of soluble factors and cell surface receptor interactions to maintain lining layer structure and promote the activation of both cell types. Key soluble interactions include production of interleukin (IL)-1 and tumor necrosis factor (TNF) by macrophages and IL-6 by fibroblasts. Adhesive interactions consist of integrin-receptor interactions as described in the text and the critical presence of homotypic interaction through cadherin-11. **B,** Sublining synovial fibroblasts interact with numerous cell types including mast cells and plasma cells (not shown), T cells, B cells, interstitial macrophages, and endothelial cells, leading to their recruitment, retention, activation, and differentiation. Both cell surface receptor interactions and secreted mediators are important in this process. T cell–fibroblast interactions include T cell recruitment and retention by fibroblast-secreted chemokines such as CXCL12, CCL5, and CX3CL1 (fractalkine). In addition, fibroblasts may activate T cells through antigen presentation, co-stimulatory receptors (e.g., CD40 and intercellular adhesion molecule-1 [ICAM-1]), and cytokine secretion. Fibroblast cytokines such as IL-6 and IL-15 may be particularly important for differentiation of the Th17 T cell subset, and secretion of interferon (IFN)-β supports T cell survival. Fibroblasts, in turn, are activated by these cell surface interactions and by T cell cytokines, including IL-17 and IFN-γ. B cells are similarly recruited and retained through fibroblast secretion of chemokines such as CXCL12 and CXCL13 and through cell surface adhesion interactions (e.g., very late activation antigen-4 [VLA-4] and vascular cell adhesion molecule-1 [VCAM-1]). Critical survival and differentiation signals are maintained through fibroblast secretion of BAFF (BLyS) and APRIL. Neutrophils and monocyte/macrophage lineage cells are also recruited by fibroblast chemokine production. Macrophages, in turn, help activate synovial sublining fibroblasts through the production of cytokines such as IL-1 and TNF. Finally, synovial sublining fibroblasts promote angiogenesis through the production of proangiogenic factors such as vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) and may help direct endothelial recruitment of inflammatory cells through secretion of cytokines such as IL-6. **C,** Pannus tissue, an extension of the hyperplastic synovial lining consisting of both activated macrophage-like synoviocyte (MLS) and fibroblast-like synoviocyte (FLS), actively degrades both cartilage and bone through production of matrix degrading enzymes such as matrix metalloproteinases (MMPs) and cathepsins. In addition, fibroblasts and T cells secrete receptor activator of nuclear factor-κB ligand (RANKL), which promotes osteoclast differentiation and activation, leading to bone erosions. Furthermore, production of dickkopf-1 (DKK1) inhibits wnt signaling pathways, which normally promote anabolic osteoblast activity, preventing repair of bone erosions. CD40L, CD40 ligand; ECM, extra-cellular matrix; FGF, fibroblast growth factor; IFNαR, interferon-α/β receptor; MHC II, type II major histocompatibility complex; TCR, T cell receptor.

molecule CXCR4 antagonist 4F-benzoyl-TN14003 ameliorated clinical severity and suppressed delayed-type hypersensitivity (DTH) responses.[95] The CXCL12/CXCR4 constitutive chemokine pair therefore seems to play an important role in lymphocyte retention in RA.

These experiments demonstrate that understanding the behavior of fibroblasts and leukocytes within microenvironments necessarily requires that we model the interactions of all the cellular populations concerned. An elegant example of this approach in vitro is the work of Lally and colleagues, who developed a flow-based model of cellular recruitment to the rheumatoid synovium.[96] Co-culturing fibroblasts from skin and RA synovial membrane with endothelial cells showed that IL-6 released from synovial (but not skin) fibroblasts was able to induce production of chemokines and adhesion molecules, resulting in greater neutrophil recruitment by synovial fibroblasts. Subsequent work interrogating the system using low-density gene arrays demonstrated that the effect of neutrophil-attracting chemokines such as CXCL5 released from synovial fibroblasts was dependent on the function of the chemokine transporter molecule DARC (Duffy antigen receptor for chemokines), which was also induced by fibroblast-to-endothelial cell co-culture.[96]

### Constitutive Chemokines and Lymphoid Neogenesis

RA is one of a number of inflammatory diseases in which the organization of the inflammatory infiltrate shares characteristics of lymphoid tissue. Follicular hyperplasia with germinal center formation can occur in autoimmune thyroid disease, myasthenia gravis, Sjögren's syndrome, and RA and may occur during infection with *Helicobacter pylori* and *Borrelia burgdorferi*. The lymphoid infiltrates in the rheumatoid synovium can be divided into at least three distinct histologic groupings, varying from diffuse lymphocyte infiltrates through organized lymphoid aggregates to clear germinal center reactions. Moreover, there is conflicting evidence that such distinct histologic types correlate with other serum indicators of disease activity. This form of inflammatory lymphoid neogenesis relies on inappropriate but highly organized temporal and spatial expression by fibroblasts of the constitutive chemokines, particularly CXCL13 and CCL21, which are required for physiologic lymphoid organogenesis.

The elegant choreography of lymphocyte-stromal interactions within lymph nodes is organized by expression of adhesive and chemotactic cues in overlapping and combinatorial fashions. Once they have encountered new antigen, DCs specialized in the presentation of antigen to lymphocytes undergo a process of maturation under the local influence of inflammatory cytokines and bacterial and viral products. As a result, inflammatory chemokine receptors are downregulated and upregulation of the constitutive receptors CCR4, CCR7, and CXCR4 occurs, causing DCs to migrate into local draining lymphatics and thereby into peripheral lymph nodes. Trafficking of B and T cells is regulated by CXCL13 (BCA-1), its receptor CXCR5, and CCL21 and CCL19 (ELC), which are both CCR7 agonists. Within the lymph node, CXCR5-bearing B cells are attracted to follicular areas, whereas T cells and DCs are maintained within parafollicular zones by local expression of CCL21 and CCL19. Some T cells that have been successfully presented with their cognate antigen by DCs then upregulate CXCR5, allowing them to migrate toward and interact with B cells.[97-99]

The genesis of lymphoid follicular structures in diseases such as diabetes and RA appears to rely on expression of such constitutive chemokines, in association with the lymphotoxins α and β (LT-α and LT-β) and TNF.[100] In this context it is important to note that transgenic animals overexpressing the TNF gene display increased formation of focal lymphoid aggregates and develop a chronic arthritis similar to RA.[101] Clearly, one of the many mechanisms of action of TNF inhibitor therapy may be the dissolution of such aggregates. In transgenic mouse models, expression of CXCL13 in the pancreatic islets was sufficient for the development of T and B cell clusters, but because they lacked follicular dendritic cells, it was not sufficient for true germinal center formation.[102] CCL21 does appear to be sufficient in some cases for lymph node formation; murine pancreatic islet models have demonstrated formation of lymph node–like structures in the presence of CCL21 and lymphoid infiltrates in response to CCL19 expression. The degree of lymphoid organization seen in the rheumatoid synovium correlates with expression of the chemokines CCL21 and CXCL13, although these chemokines are also associated with less organized lymphoid aggregates.[103] Expression of CCL21 is restricted to a population of perivascular fibroblastic reticular cells with common phenotype and function in secondary lymphoid and inflammatory aggregate tissues.[104] CXCR5 is overexpressed in the rheumatoid synovium, consistent with a role in recruitment and positioning of B and T lymphocytes within lymphoid aggregates of the RA synovium. It therefore seems likely that expression of lymphoid-constitutive chemokines contributes significantly to the entry, local organization, and exit of lymphocytes in the RA synovium. It also seems that the ectopic expression of chemokines is a general characteristic of a number of chronic rheumatic conditions because another B cell–attracting chemokine CXCL13 (BCA-1) is inappropriately expressed by fibroblasts in the salivary glands of patients with Sjögren's syndrome.[105]

Interestingly, the ectopic lymphoid structures seen in RA are capable of appropriate secondary lymphoid tissue structures, including the production of class-switched high-affinity antibody production, as evidenced by the expression of activation-induced cytidine deaminase (AID), the enzyme required for somatic hypermutation and class switch recombination (CSR) of Ig genes.[106] CXCR3-expressing plasma cells are also present in the rheumatoid synovium, and their recruitment is once more supported by ectopic production of the CXCR3 ligand CXCL9 by fibroblasts, particularly in the sublining region where aggregates are located.[107]

## Role of Fibroblast Subsets in Disease

It is possible that the various potential sources of expanded populations of synovial fibroblasts discussed earlier may correspond with functionally diverse fibroblast lineages and subpopulations. Through use of microarray analysis, Kasperkovitz and collaborators showed that the transcriptional profile of RA synovial fibroblasts clustered into two

broad groups representing "high" (myofibroblastic) and "low" (growth factor producing) populations.[5] These clusters were shown to be representative of the heterogeneity and of the degree of inflammation in the tissue of origin, suggesting that transcriptionally and functionally distinct populations of fibroblasts exist in joints. For example, some $CD248^+$ cells may correspond with a pluripotential, stem cell–like population of pericytic cells lying in close apposition to endothelial cells, which provide a supply of new stromal cells during inflammation.[108] Interestingly, deletion or removal of the intra-cellular portion of CD248 can reduce stromal cell accumulation and ameliorate models of arthritis such as murine collagen antibody-induced arthritis (CAIA).[109] Furthermore, the prevailing conditions of hypoxia within the rheumatoid synovium may enhance expression of CD248, which is regulated by hypoxia-inducible factor-2 (HIF-2) binding to a hypoxia response element, and which in turn participates in angiogenesis.[110]

Whether such markers remain associated with functionally distinct subpopulations or simply contribute to a larger local pool of multipotential mesenchymal precursors is as yet unknown, but the discovery of markers apparently linked to function has provided the tools with which such questions can be answered. The surface marker gp38 (podoplanin) is a potential therapeutic target that marks populations of fibroblasts (fibroblastic reticular cells) that modulate trafficking of immune cells such as dendritic cells within the lymph node.[48] The surface marker gp38 is highly expressed in lining layer fibroblasts in RA, and its synovial expression has been shown to be reduced during TNF blockade. In vitro data support a relationship with inflammation, because gp38 expression is induced by pro-inflammatory cytokines, whereas silencing reduces IL-6 and IL-8 production.[111,112] The results of studies demonstrating the association of stromal subpopulations with disease outcomes and response to therapy are eagerly awaited, as are the first attempts to target stromal markers therapeutically. The other group of markers that has been associated with synovial fibroblasts has come from the field of oncology.

## Epigenetic Regulation of Fibroblast Gene Expression in Rheumatic Disease

Epigenetic regulation implies heritable alterations in regulation of gene transcription in the absence of genetic mutation. The epigenetic code, itself regulated by dedicated enzyme complexes, consists of two main groups of covalent modifications: first, methylation and hydroxymethylation of CpG dinucleotides in DNA gene promotor regions, and second, multiple modifications of the histone proteins around which DNA is packaged in chromatin, including acetylation, methylation, and citrullination[113]; these modifications control the access of transcription complexes to chromatin. Global changes in DNA methylation have been recorded in RA FLS, paralleling those seen in human tumors; using demethylating agents to induce global DNA demethylation in "normal" synovial fibroblasts induces genes suggestive of change toward an RA FLS-like phenotype.[114] Similarly, global changes in histone acetylation and levels of the histone acetyltransferase (HAT) and histone deacetylase (HDAC) complexes that are responsible for their control have been demonstrated in RA FLS.[115,116] HDAC inhibitors have also been suggested to show beneficial effects in vitro and in ex vivo models using synovial tissue.[117,118]

Transcriptomics has been used to identify genes overexpressed in RA FLS, which has identified promoter hypomethylation in the critical T-box transcription factor 5 *(TBX5)* gene and specific local histone modifications such as histone 4 lysine 4 trimethylation that correspond with open chromatin structure and active transcription. TBX5 emerges as a target of cytokine (IL-1β) and TLR stimulation and a driver of multiple pathways, including chemokine expression, thus identifying a key element in the epigenetic regulation of established RA FLS.[119] Other genes recently identified as subject to epigenetic regulation in RA FLS include the cytokine IL-6[120] and the chemokine CXCL12.[121] Cytokine stimulation can regulate promoter DNA methylation, demonstrating a reversible, short-term hypomethylation of candidate genes in response to IL-1β in OA and RA fibroblasts mediated via changes in DNA methyltransferase activity. However, although this suggests that pro-inflammatory cytokines can drive epigenetic regulation, the repertoire of promoters modified by IL-1β exposure was limited, suggesting that additional factors influence the persistent changes seen in long-standing disease.[122] Whole methylome comparative analysis of RA FLS and OA FLS reveals epigenetic change in key genes, including the key signaling component STAT3, and MAP3K5 (ASK1), a key component of TLR-induced inflammatory pathways and apoptosis in response to cellular stress.[123,124]

Rapid advances helped define the altered, profibrotic phenotype of fibroblasts in systemic sclerosis. Once again initial studies have focused on genome-wide regulation; blockade in dermal fibroblasts of histone 3 lysine 27 trimethylation, a well-characterized histone modification associated with gene silencing, led to dramatic increases in collagen release in vitro and in animal models of fibrosis.[125] Focused work on proteins interacting with Wnt pathways that regulate both bone turnover and fibrotic processes revealed hypermethylation of the promoters of DKK1 and SFRP1. Use of the whole genome demethylating agent 5-aza-cytidine reversed this modification and ameliorated experimental fibrosis.[126] Although this represents a non-specific approach to modifying regulation of individual genes, 5-aza-cytidine is already in use in the treatment of multiple myeloma, and such drugs are the precursors of newer agents that will target regulation of specific groups of genes via blockade of regulatory subunits of the chromatin modifying complexes that generate and remove epigenetic modifications.[127]

Proof of the concept that epigenetic regulation determines disease phenotype comes from a recent genome-wide DNA methylation study comparing fibroblasts from scleroderma patients with diffuse disease, patients with limited disease, and control subjects. Not only were differentially methylated DNA sites found between the groups, but these sites were also frequently related to key genes in fibrotic pathways, including the metalloprotease ADAM12, collagen genes, and transcription factors of the RUNX family that are known to drive collagen synthesis. Multiple additional candidates identified by this study will further elucidate the roles and interactions of fibroblasts in scleroderma.[128]

Targeting global epigenetic change, although a potential therapeutic in the context of a hematologic malignancy such as myeloma, is unlikely to be acceptable in the treatment of chronic inflammatory disease, as reflected in the high levels of adverse events seen in early phase trials in persons with juvenile idiopathic arthritis (JIA).[129] Our ability to target specific epigenetic modification complexes and thus influence individual genes or groups of genes is currently limited[130] but will rapidly expand over coming years.

### MicroRNAs and Fibroblast-like Synoviocytes

MiRNAs are small, approximately 22-nucleotide-long RNAs that regulate the expression of multiple genes through interactions with both the 3′ untranslated region (UTR) of gene transcripts and RNA-induced silencing complexes.[131] This in turn interferes with translation of messenger RNA (mRNA) into protein or induces mRNA degradation. Currently around 1900 miRNAs have been identified in humans, although many of the target genes of miRNAs are yet to be described.

MiRNAs are frequently grouped alongside epigenetic modifications as key controllers of altered gene expression in disease. Underlying this association is the high degree of epigenetic regulation of miRNA genes. This phenomenon has been demonstrated at the level of individual genes, as in the case of miR-203, which is overexpressed in RA FLS under the control of DNA methylation, leading to enhanced expression of MMPs and IL-6.[132] A similar regulatory relationship has also been demonstrated at a whole genome level: Comparing RA FLS and OA FLS, a range of differentially expressed miRNAs were identified and shown to be in close proximity to differentially methylated CpG rich regions of DNA, suggesting that differences in miRNA profiles are closely related to DNA methylation. These differential CpG region methylation and miRNA expression data sets have been further combined in silico to predict networks of miRNA targets that may be modified in the aggressive RA FLS phenotype.[133]

Two miRNAs, miR-146a and miR-155, are vital for immune function, are overexpressed in RA FLS compared with OA FLS, and are subject to induction by cytokines and TLR ligands. The miRNA miR-155 drives changes in MMP repertoire,[134] although in vitro studies suggest a regulatory role leading to overall repression of MMP production.[135] The importance of miR-146a in anti-inflammatory regulatory networks has been highlighted through work with the arthritogenic Chikungunya virus. Chikungunya virus–infected synovial fibroblasts upregulate miR-146a, which in turn downregulates pro-inflammatory signaling factors such as TRAF6, IRAK1, and IRAK2, resulting in a corresponding decrease in NF-κB phosphorylation. This finding highlights the critical involvement of this miRNA in the regulation of inflammation.[136]

Increased RA FLS survival is linked to miRNAs; the miR-34 promoter becomes hypermethylated in RA FLS, leading to reduced responsiveness to FasL and TNF-related apoptosis-inducing ligand (TRAIL)-mediated apoptosis.[137] More recently, mutations in p53 in RA have been linked to miRNA-regulated proliferation of RA FLS; mutated forms of p53 are not capable of driving the expression of miR-22, which represses the pro-proliferation protein Cry61. This finding fits with observations of decreased miR-22 expression in RA compared with OA synovial tissue, providing a potential explanation for increased RA FLS numbers in the synovium.[138] MiR-20 has also been implicated in regulation of cell survival and inflammation; overexpression of MiR-20 in RA FLS reduced ASK1 mRNA stability and inhibited LPS-induced IL-6 and CXCL10 expression.[139] This finding adds to the increasing data demonstrating a role for miRNAs in regulation of TLR-induced responses; for example, previous work has shown that miR-19a/b regulate TLR2 expression in RA FLS.[140]

Modulation of miRNA expression has significant therapeutic potential as a means of regulating networks of related genes rather than current approaches targeting single cytokines or cell types. Multiple approaches are being taken to develop miRNA therapeutics, including administering exogenous miRNAs and treatment with compounds that either stimulate or inhibit the expression of endogenous miRNAs. For instance, the compound denbinobin upregulates the expression of miR-146a, which in turn ablates the responsiveness of OA FLS to IL-1β.[141]

## Lessons Learned from Cancer

Alongside the field of inflammation, oncology has also been experiencing a surge in interest in the biology of fibroblasts and stromal cells, as well as the mechanisms by which they interact with primary transformed tumor cells.[142] A number of important cytokines that contribute to cancerous transformation of healthy cells by so-called cancer-associated fibroblasts have been described, including hepatocyte growth factor (HGF) and TGF-β. Crucially, tumor-associated fibroblasts appear able to transform normal cells, in addition to premalignant cells.[142] The importance of tumor-associated fibroblasts, termed cancer-associated fibroblasts (CAFs), has been demonstrated in breast cancer: human breast cancer implants were unable to grow successfully when implanted into mice without their co-administration with human tumor–derived fibroblasts.[143] Intriguingly, similar molecular signals have been implicated in the predilection for cancer cells to metastasize to certain sites. In particular, the ectopic expression and function of the CXCL12/CXCR4 ligand-receptor pair, in a manner reminiscent of RA, has been implicated in the persistence and tissue tropism of metastatic cells in breast cancer. Tumor-associated fibroblasts secrete CXCL12, resulting in increased promotion of carcinoma cell proliferation, migration, and invasion compared with control fibroblasts but also leading to recruitment of endothelial cell precursors.[144,145]

Furthermore, molecules that mark fibroblast subpopulations in the joint are associated with active, invasive cancer. These molecules include the expression of tumor-associated stromal markers such as fibroblast activation protein (FAP),[12, 13] galectin-3,[146,147] and S-100A4.[148] Interestingly, galectin-3 has been shown to be subject to epigenetic regulation.[147,149] Both gp38 and CD248 are also heavily implicated in tumor progression.[9,150]

These similarities between RA synovial fibroblasts and CAFs overlap with observations that the persistent phenotype of RA synovial fibroblasts itself includes elements

normally associated with "transformed" cells. These elements include loss of density and anchorage limitation for growth, which usually curtails in vitro fibroblast culture, firm adherence to ECM components of cartilage, and the invasiveness that is most aptly demonstrated in the chimeric SCID mouse model. Another defining characteristic of RA synovial fibroblasts that helps to explain their phenotype is dysregulation of proto-oncogenes and tumor suppressor genes. Once again, epigenetic regulation is likely to underlie this phenotype. However, the precise mechanisms maintaining the persistent phenotype at a whole genome level are yet to be elucidated.

Furthermore, RA is a systemic disease involving multiple joints; therefore, whether the fibroblast phenotype results from a global change in fibroblast gene expression or whether the phenotype is locally imprinted by exposure to a characteristic cytokine, matrix, and cellular milieu is yet to be established. Recent data now appear to confirm that human RA synovial fibroblasts within the SCID mouse model may travel systemically through lymphatics and the bloodstream to unpopulated samples of cartilage and then invade.[19] Therefore, at least one possibility is that locally imprinted, "activated" fibroblasts may export destructive arthritis to joints where mild injury or immune response has occurred over time. In the cancer field, the concept of tumor stroma "normalization" has now become an accepted aspect of new oncology therapies. Clinical studies of angiogenesis inhibitors and antibodies against ECM components such as tenascin have been favorable, whereas inhibitors of MMPs, overexpression of TIMPs, and blockade of integrin signaling have all shown promise in pre-clinical trials.[151] Results of studies examining the interactions between endothelial cells and their associated pericytes underlie the importance of targeting the stroma as a whole. Bergers and colleagues[152] have shown that endothelial cells release PDGF, which induces VEGF production from pericytes, leading to bidirectional conversations between the two cell types. Interrupting these conversations by using PDGF inhibitors proved to be more effective therapy than using VEGF inhibitors alone. Interestingly, although VEGF inhibitors lost their inhibitory effect in later stage tumors, targeting of the pericytes helped even late-stage tumors to regress.[152] The authors have subsequently shown that pericyte precursors are partly recruited from the bone marrow to tumor perivascular sites.[153]

The cyclin-dependent kinases (CDKs) are a family of enzymes that maintain cellular proliferation and survival under tight control, balanced by specific inhibitors (CDKis). CDK dysregulation has been demonstrated in many tumors, and their manipulation has consequently been exploited to develop anticancer drugs including the CDKi roscovitine.[154] RA fibroblasts express low levels of the CDKi p21,[155] and adenovirus-mediated p21 gene transfer into RA fibroblasts both induces cell cycle arrest and downregulates expression of cytokines, MMPs, and cathepsins,[156] suggesting a novel therapy targeting a disease-specific phenotype in RA FLS. Inhibition of TNF pathways and CDK inhibition have recently been shown to synergize in ameliorating murine collagen-induced arthritis without increasing immune suppression. This approach, currently in early phase trials in RA, may therefore have significant benefits.[157]

## CONCLUSION

Fibroblasts are structural mesenchymal cells that form the cellular infrastructure for most internal organs, as well as for bordering membranes such as the synovial membrane. They are prominently involved in the deposition and resorption of the ECM and thus are responsible for maintaining tissue homeostasis. However, fibroblasts are far more than structural, passively responding cells that build the "backbone" for organ-specific function. Rather, they are sensitive to environmental changes. They react in a specific manner to a variety of stimuli and are capable of actively influencing not only the composition of the ECM but also the cellular composition of tissues and barrier membranes. Under inflammatory disease conditions, fibroblasts act as organ-specific, innate immune system sentinel cells and are involved in the progression of organ damage, as well as in the switch from acute resolving to chronic persisting inflammation. We now know that functionally distinct fibroblast subsets exist and can be identified with new markers to understand better mechanisms of developmental patterning, wound healing, and persistent inflammatory responses, which appear to depend in large part on epigenetic modifications. This notion is particularly true for fibroblast-like synoviocytes, which play a critical role in the pathogenesis of RA and possess a characteristic, invasive, and activated phenotype. In addition to contributing to the recruitment of inflammatory cells to the joint, they modulate the survival and behavior of these cells and are, in turn, regulated by the newly recruited cells. More importantly, fibroblast-like synoviocytes are crucial components in the hyperplastic lining layer and in cartilage destruction. New data raise the possibility of epigenetically programmed aggressive cells exporting arthritis from inflamed to uninflamed joints in the early stages of arthritis, but at the same time offering the possibility of specifically targeting stromal subpopulations of choice.

CHAPTER 15

# Mast Cells

Peter A. Nigrovic

**KEY POINTS**

- Mast cells arise in the bone marrow, circulate as immature precursors, and develop into functional mast cells after entering peripheral tissues.
- The phenotype of mast cells is diverse, plastic, and governed by signals from lymphocytes, fibroblasts, and other elements of the microenvironment.
- In healthy tissues, mast cells serve as immunologic sentinels and participate in innate and adaptive immune responses to bacteria and parasites.
- Mast cells accumulate in injured and inflamed tissue, where they may amplify or suppress inflammation.
- Mast cells have been implicated in multiple immune-mediated diseases, including inflammatory arthritis, although their role as a therapeutic target remains uncertain.

Although mast cells are best known for their role in allergy and anaphylaxis, the immune function of this bone marrow–derived lineage far outstrips its participation in immunoglobulin (Ig)E-driven disease. Mast cells are resident broadly in vascularized tissues but cluster near interfaces with the external world, in the linings of vulnerable body cavities, and near blood vessels and nerves. In these locations, mast cells serve as immune sentinels and are equipped with an array of pathogen receptors, along with an armamentarium of mediators capable of rapidly recruiting immune effector cells. Mast cells also accumulate in sites of tissue injury and chronic inflammation, although their role in such locations remains uncertain. Other functions for this lineage, conserved by evolution for more than 500 million years, continue to be defined.

Circumstantial and experimental evidence implicates mast cells in the pathogenesis of rheumatic diseases. Mast cells reside constitutively in the normal synovium and are found in large numbers in inflamed synovial tissue, whereas mast cell mediators are identified in inflammatory joint fluid. Moreover, models have indicated that mast cells can make an important contribution to the pathogenesis of experimental arthritis. Mast cells have also been implicated in other autoimmune conditions, including multiple sclerosis, bullous pemphigoid, and systemic sclerosis.

## BASIC BIOLOGY OF MAST CELLS

### Development and Tissue Distribution

Mast cells are distinctive in appearance. Ranging in size from 10 to 60 μm and with a centrally located round or oval nucleus, their abundant cytoplasm is filled with multiple small granules. They were named *Mastzellen* in 1878 by the German pathologist Paul Ehrlich, who believed that they were overfed connective tissue cells (*mästen*, in German, means to feed or fatten an animal).[1] Electron microscopy reveals that the plasma membrane of the mast cells exhibits multiple thin cytoplasmic extensions, providing a broad interface with the surrounding tissue (Figure 15-1A). The tissue distribution of mast cells is extensive; within tissue, mast cells tend to cluster around blood vessels and nerves and near epithelial and mucosal surfaces. They are also found in the lining of vulnerable body cavities such as the peritoneum and the diarthrodial joint. Given this localization, mast cells are among the first immune cells to encounter pathogens invading into tissue from the external world or via the bloodstream, consistent with their role as immune sentinel cells.

Mast cells are of hematopoietic origin, arising in the bone marrow and depositing in tissues after migrating through the bloodstream[2,3] (Figure 15-2). Unlike other myeloid cells, such as monocytes and neutrophils, mast cells do not terminally differentiate in the bone marrow but rather circulate as progenitors, bearing the surface signature $CD34^+/c\text{-}Kit^+/CD13^+$.[4] Further developmental details have been worked out most extensively in the mouse. A burst of circulating progenitors late in gestation suggests the possibility that mast cells may populate the tissues primarily during early development, with later recruitment restricted to the inflammatory context, as appears to be the case for certain populations of murine tissue macrophages.[3] After entering the tissues, murine mast cells may mature into classic granulated cells or remain as ungranulated progenitors, awaiting local signals to differentiate fully. Comparison of murine lung and intestine has demonstrated that these tissues use distinct pathways to regulate the constitutive and inducible recruitment of mast cell progenitors, illustrating that mast cell homing is a precisely controlled process.[5,6]

Once resident in tissues, mast cells may live for many months. Mature mast cells remain capable of mitotic division, although recruitment of circulating progenitors appears

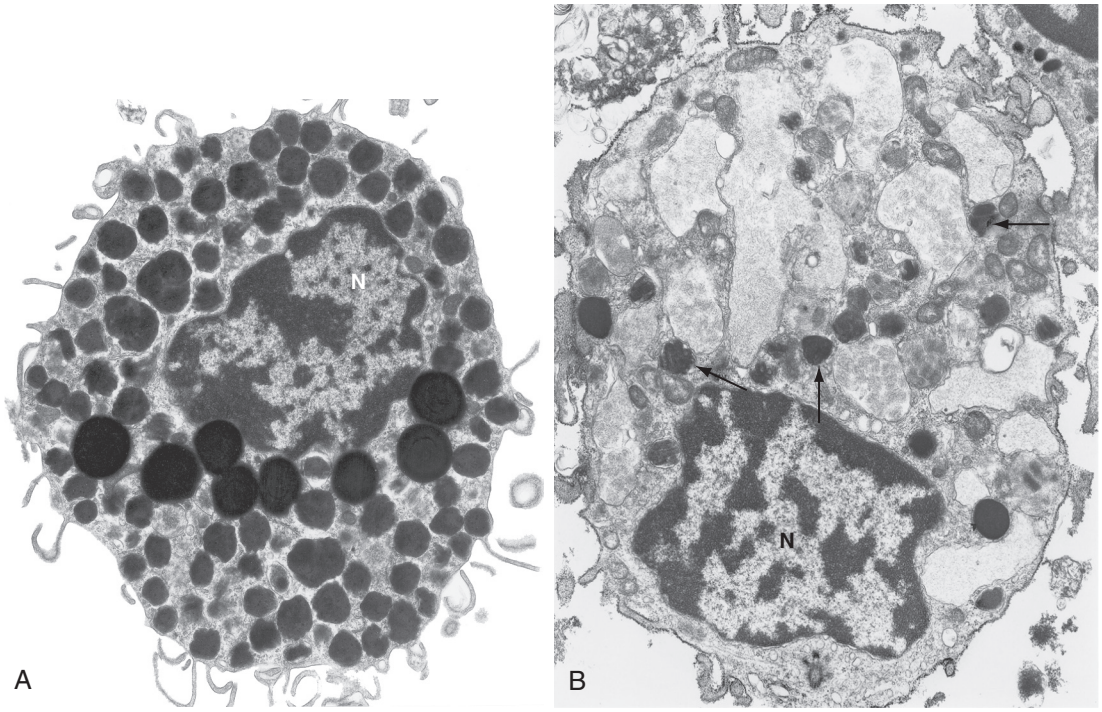

**Figure 15-1** Mast cell morphology. **A,** An intact mast cell. **B,** A mast cell that has undergone anaphylactic degranulation. Note how fusion of intracellular granules has resulted in the formation of a labyrinth of interconnected channels by which granule contents may be expelled from the cell. Arrows indicate remaining granules. N, Nucleus. *(Images courtesy Dr. A. Dvorak, Beth Israel Deaconess Medical Center, Boston, Mass. From Dvorak AM, Schleimer RP, Lichtenstein LM: Morphologic mast cell cycles,* Cell Immunol *105:199–204, 1987; and Galli SJ, Dvorak AM, Dvorak HF: Basophils and mast cells: morphologic insights into their biology, secretory patterns, and function. In Ishizaka K, editor:* Progress in allergy: mast cell activation and mediator release, *Basel, 1984, S Karger, pp 1–141.)*

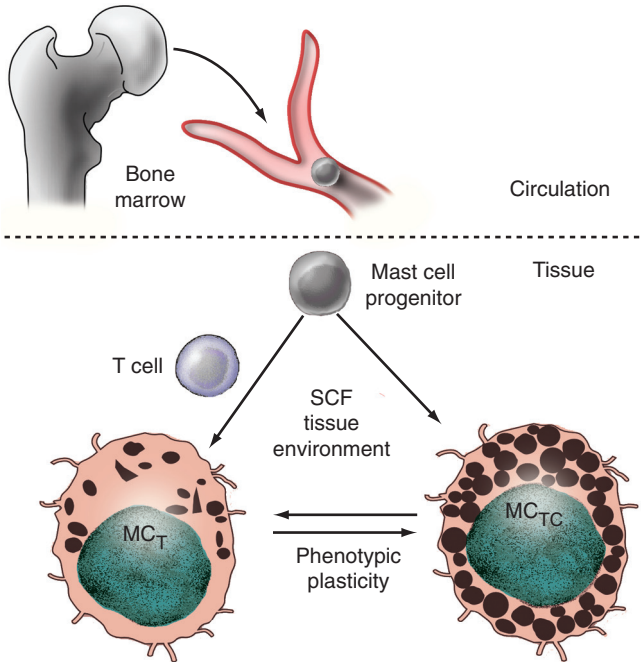

**Figure 15-2** Mast cell origin and differentiation. Mast cells arise in the bone marrow, circulate as committed progenitors, and differentiate into mature mast cells upon entering tissue. Human mast cells may be classified on the basis of granule proteases into tryptase$^+$ mast cells ($MC_T$) and tryptase$^+$/chymase$^+$ mast cells ($MC_{TC}$), with characteristic tissue localization and mediator production. SCF, Stem cell factor.

to greatly exceed local replication as a pathway to expand the number of tissue mast cells. Mechanisms of reducing mast cell numbers include apoptosis, as demonstrated in tissue mast cells deprived of the cytokine stem cell factor (SCF), a critical survival signal for mast cells.[7] Under certain conditions, mast cells can also emigrate via the lymphatics, appearing in draining lymph nodes much in the manner of dendritic cells.[8] The pathways that license mast cell accumulation in inflamed tissues are incompletely defined but include tissue production of factors such as interleukin (IL)-4 and IL-33 that attenuate mast cell apoptosis.[9,10]

## Mast Cell Heterogeneity: Common Progenitor, Multiple Subsets, and Phenotypic Plasticity

Whereas all types of mast cells derive from a common progenitor lineage, the phenotype of fully differentiated tissue mast cells is heterogeneous. Human mast cells are conventionally divided into two broad classes on the basis of the protease contents of their granules (Figure 15-2). $MC_{TC}$ display rounded granules that contain the enzymes tryptase and chymase, whereas the smaller, and more irregularly shaped granules of $MC_T$ contain tryptase but not chymase. $MC_{TC}$ also express other proteases, including carboxypeptidase and cathepsin G. These subtypes differ in tissue distribution. $MC_{TC}$ tend to be found in connective tissue, such as in normal skin, muscle, the intestinal submucosa, and the normal synovium, whereas $MC_T$ predominate in

mucosal sites, including the lining of the gut and respiratory tract, although in fact both are present in many locations. Beyond the protease signature, other differences between these subsets include their profile of cytokine elaboration, as well as cell surface receptor expression; however, tissue-specific phenotypic differences are noted within each type as well (i.e., neither $MC_{TC}$ nor $MC_T$ are homogenous cellular subsets).

The relationship between $MC_{TC}$ and $MC_T$ mast cells is controversial. Are they committed subsets, akin to CD4 and CD8 lymphocytes, or are they functional states assumed by mast cells under the influence of the microenvironment? In mice, in which an analogous distinction exists between connective tissue mast cells (CTMCs) and mucosal mast cells (MMCs), evidence for phenotypic plasticity is strong. Both in culture and in vivo, single CTMCs may differentiate into (or give rise to) MMCs and vice versa.[11,12] Mast cells with intermediate protease expression are found, and serial observations suggest that exposure to an inflammatory stimulus can induce progressive change from one class to another, although whether this change occurs at a single-cell level has not been definitively established.[13] Similarly, in murine and human mastocytosis, clonally expanded mast cells display divergent phenotypes depending on the tissue of residence.[14,15] In aggregate, these data favor the hypothesis that mast cells assume a particular phenotype under the control of the local signals but can alter this phenotype if conditions change.

## Stem Cell Factor

One of the most important signals from tissue to local mast cells is SCF. The receptor for SCF, c-Kit, is expressed widely on hematopoietic lineages early in differentiation, but among mature lineages, only mast cells express c-Kit at a high level. Stimulation of mast cells by SCF promotes maturation and phenotypic differentiation, blocks apoptosis, and induces chemotaxis. It may also activate mast cells directly to release mediators. In both mice and humans, SCF remains an irreplaceable survival signal for tissue mast cells. Accordingly, mice with defects in SCF or c-Kit are strikingly deficient in mature tissue mast cells (examples include $W/W^v$, $Sl/Sl^d$, and $W^{sh}$ mouse strains). Similarly, clonal mast cells obtained from patients with systemic mastocytosis commonly exhibit activating mutations in *c-kit*.

SCF occurs in two alternate forms resulting from differential mRNA splicing: soluble and membrane bound. The importance of this latter form is clear from $Sl/Sl^d$ mice, which lack only the membrane-bound isoform yet exhibit very few tissue mast cells.[16] SCF is synthesized by multiple lineages, including mast cells themselves. Expression by fibroblasts is especially important, given the intimate physical contacts observed between fibroblasts and mast cells in situ. The SCF/c-Kit axis mediates cell-cell adhesion between mast cells and fibroblasts independent of the kinase activity of the receptor.[17] Rodent mast cells co-cultured with fibroblasts demonstrate enhanced survival, connective-tissue phenotypic differentiation, and heightened capacity to elaborate pro-inflammatory eicosanoids, effects mediated at least in part by direct contact, including interactions between SCF and c-Kit.[18,19] The extent of similar regulation in human mast cells is uncertain.[20] Expression of SCF has also been documented on other lineages including macrophages, vascular endothelium, and airway epithelium and is likely a critical pathway by which tissues modulate the local mast cell population.

## T Lymphocytes and Other Cells

T lymphocytes exert a profound effect on mast cell phenotype. Severe combined immunodeficiency (SCID) mice that lack T cells fail to develop mucosal mast cells, a defect that can be corrected by T cell engraftment.[21] An analogous observation has been made in humans deficient in T cells due to congenital immunodeficiency or acquired immunodeficiency syndrome (AIDS). Intestinal biopsy in these patients shows that MMCs ($MC_T$) are strikingly reduced, whereas CTMCs ($MC_{TC}$) are present in normal numbers.[22] The pathways by which T cells exert this striking effect are not defined, although it is clear that T cell cytokines such as interleukin (IL)-3, IL-4, IL-6, IL-9, and transforming growth factor (TGF)-β may have profound effects on the phenotype of mast cells matured in culture. By contrast, interferon (IFN)-γ inhibits mast cell proliferation and may induce apoptosis. These observations imply that cells recruited to an inflamed tissue may have a profound impact on the phenotype of local mast cells. The rheumatoid synovium may well exemplify this phenomenon. The synovium is normally populated by $MC_{TC}$ mast cells, but large numbers of $MC_T$ mast cells are identified in the inflamed synovium, typically in regions rich in infiltrating leukocytes, whereas $MC_{TC}$ mast cells reside in deeper, more fibrotic areas of the joint.[23] Interestingly, regulatory T cells (Treg cells) can also have a direct impact on mast cell function, including recruitment, receptor expression, degranulation, and cytokine production.[24-27]

Other cells aside from T cells can potentially interact with mast cells in the tissues. In particular, fibroblasts and mast cells commonly demonstrate close physical interactions. Beyond SCF, fibroblasts elaborate cytokines such as the IL-1 family member IL-33, which can exert effects on mast cell protease expression, effector phenotype, and survival.[10,28,29] Dendritic cells have also been implicated in the recruitment of mast cells into inflamed tissues.[30]

## Different Functions for $MC_T$ and $MC_{TC}$ Mast Cells

The preservation of distinct types of mast cells in multiple species implies distinct and nonoverlapping roles for these subtypes. However, the understanding of functional differences between $MC_T$ and $MC_{TC}$ remains limited. One hypothesis is that $MC_T$ play a pro-inflammatory role and $MC_{TC}$ specialize in matrix remodeling.[31] This hypothesis makes sense of (1) the promotion of $MC_T$ development by T cells patrolling the tissues; (2) the partition of $MC_T$ and $MC_{TC}$ mast cells to inflamed and fibrotic areas, respectively; and (3) the preferential expression of the pro-inflammatory mediators IL-5 and IL-6 by $MC_T$ and the profibrotic IL-4 by $MC_{TC}$.[32] Not all observations fit comfortably into this dichotomy, however. For example, the potently pro-inflammatory anaphylatoxin receptor C5aR (CD88) is expressed on $MC_{TC}$ but not on $MC_T$ [33]. Ultimately, too little is known about the actual functional importance of these subsets to permit firm conclusions.

## Mast Cell Activation

### Immunoglobulin E

The canonical pathway to mast cell activation is via IgE and its receptor FcεRI. With a $K_a$ of $10^{10}$/M, this receptor is essentially constantly saturated with IgE at typical serum concentrations. Such binding not only sensitizes mast cells to the target antigen but also helps promote mast cell survival and, in some cases, cytokine production. Cross-linking FcεRI-bound IgE by multivalent antigen induces a brisk and vigorous response. Within minutes, granules within the mast cell fuse together and with the surface membrane, creating a set of labyrinthine channels that allow rapid release of granule contents (see Figure 15-1B).[34] This compound exocytosis event, termed *anaphylactic degranulation*, is followed within minutes by the elaboration of eicosanoids newly synthesized from arachidonic acid cleaved from internal membrane lipids. Finally, signals transduced via FcεRI induce the transcription of new genes and elaboration of a wide range of chemokines and cytokines (Figure 15-3). Upon termination of the stimulation event, the surface membrane closes over the granule-formed channels, which subsequently bud off within the cytoplasm, re-creating discrete granules using the original membranes.[34] These granules are then recharged with mediators in a process that occurs gradually over days to weeks.[35]

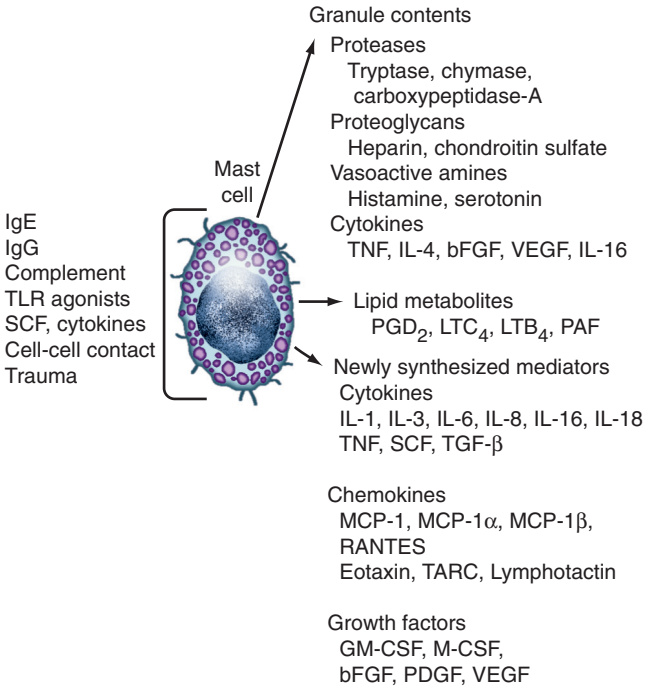

**Figure 15-3** Mediator production by human mast cells (partial list). The set of mediators liberated upon activation will vary depending on the state of differentiation of the mast cell and the nature of the stimulus. See Reference 91 for a complete mediator list and references. bFGF, Basic fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; Ig, immunoglobulin; $LTB_4$, leukotriene $B_4$; $LTC_4$, leukotriene $C_4$; MCP, monocyte chemoattractant protein; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; $PGD_2$, prostaglandin $D_2$; RANTES, released upon activation, normal T-cell expressed and secreted; SCF, stem cell factor; TARC, thymus and activation-regulated chemokine; TGF-β, transforming growth factor-β; TLR, toll-like receptor; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

### Immunoglobulin G and Immune Complexes

IgE is only one among many pathways of mast cell activation. One key trigger for mast cell activation in both human and mouse is IgG, acting via receptors for the Fc portion of IgG (FcγR). The importance of this pathway was demonstrated first in mice rendered genetically deficient in IgE. Contrary to expectations, these animals remain susceptible to anaphylaxis mediated through IgG and the low-affinity IgG receptor FcγRIII.[36,37] The human counterpart of this receptor, FcγRIIa, is equally capable of inducing activation of human mast cells.[38,39] Human mast cells can also be induced to express the high-affinity IgG receptor FcγRI, rendering them susceptible to IgG-mediated activation.[40,41]

These IgG receptors contribute to involvement of mast cells in IgG-driven diseases. Thus, in the mouse, mast cells participate in IgG-mediated immune complex peritonitis, the cutaneous Arthus reaction, and experimental murine bullous pemphigoid.[42-44] Activation via Fc receptors also mediates mast cell participation in antibody-mediated murine arthritis.[45]

### Soluble Mediators and Cell-Cell Contact

Mast cells coordinate with immune and nonimmune cell lineages via mechanisms beyond antibody response, including soluble mediators and surface receptors. Examples of such signals include the cytokine tumor necrosis factor (TNF) and the neurogenic peptide substance P, which can induce mast cell degranulation.[46,47] Physical contact with other cells can also induce mast cell activation. For example, CD30 on lymphocytes can interact with CD30L on mast cells to induce the production of a range of chemokines.[48] Interestingly, ligation of CD30L does not induce release of granule contents or lipid mediators, illustrating the selectivity of response of which mast cells are capable.

### Danger and Injury

Mast cells are equipped to recognize danger in the absence of guidance from other lineages via a range of pathogen receptors, including multiple toll-like receptors (TLRs) and CD48, a surface protein recognizing the fimbrial antigen FimH. These receptors are implicated in the response of mast cells to pathogens and could potentially contribute to mast cell engagement in diseases such as atopic dermatitis, in which skin becomes abnormally colonized with bacteria.[49,50] Mast cells may also be activated through complement, including the anaphylatoxins C3a and C5a.[39,47] Mast cells can respond directly to physical stimuli including trauma, temperature, and osmotic stress.[51] Finally, mast cells can be triggered by danger signals released by injured bystander cells, such as IL-33 and monosodium urate crystals.[52-54] Together, these receptors enable mast cell involvement in a broad range of immune and nonimmune processes.

### Inhibitory Signals for Mast Cells

As with other immune lineages, mast cells are subject to both negative and positive regulation. Cytokines that inhibit aspects of mast cell function include TGF-β and

IL-10.[55,56] Examples of inhibitory receptors on the surface of mast cells include the IgG receptor FcγRIIb and the phosphatidyl serine receptor CD300A. The importance of these receptors is demonstrated in genetically deficient animals. Mice lacking FcγRIIb demonstrate a striking propensity to activation via both IgG and IgE (which binds with low affinity to both FcγRIIb and FcεRI).[57,58] CD300A mediates suppression of mast cell activation by apoptotic debris.[59] Modulating the surface expression of inhibitory receptors is a potentially important mechanism for regulation of the activation threshold of mast cells in tissues.

## Mast Cell Mediators

### Granule Contents: Proteases, Amines, Proteoglycans, and Cytokines

Mature mast cells package a range of mediators in their granules that are ready for immediate release through fusion with the surface membrane. The most abundant of these mediators are the neutral proteases, named for their enzymatic activity at neutral pH, but vasoactive amines, proteoglycans such as heparin, and certain pre-formed cytokines play distinct roles in the biologic consequences of mast cell degranulation. The release of these mediators is not all or none. In addition to anaphylactic degranulation, mast cells may release only a few granules at a time in a process termed *piecemeal degranulation*.[60] Further, mast cells can release one type of granule but not another.[61] Alternately, mast cells may be induced to elaborate cytokines and chemokines without any release of granule contents, as illustrated by activation via CD30L.[48] Thus, although the mast cell is well equipped to release large volumes of pre-formed mediators, it is equally capable of responses tailored to the activating stimulus.

**Tryptase.** Named for its enzymatic similarity to pancreatic trypsin, tryptase is the most abundant granule protein in human mast cells. It is also an essentially specific marker for mast cells. Tryptase is synthesized in scant amounts by basophils but by no other lineage. The enzyme found in granules is the β isomer, which is the product of two distinct genes. It is enzymatically active upon formation of a homotetramer that relies on the scaffolding function of the proteoglycan heparin.[62] Mast cells also synthesize α tryptase, a protein incapable of forming homotetramers and thus enzymatically inactive. Unlike β tryptase, the α isomer is not stored in granules but is constitutively released into circulation, where its function is unknown. The distinction between tryptase isomers is important for diagnostic reasons: as a marker of degranulation, systemic levels of β tryptase constitute a marker of recent anaphylaxis.[63] By contrast, α trypsin levels reflect total body mast cell load and serve as a useful biomarker in systemic mastocytosis.[64]

Tryptase cleaves structural proteins such as fibronectin and type IV collagen and enzymatically activates stromelysin, an enzyme responsible for activating collagenase.[65] Fibrinogen is another substrate, potentially implicating mast cells in prevention of fibrin deposition and blood coagulation in the tissues.[66] Tryptase also promotes hyperplasia and activation of fibroblasts, airway smooth muscle cells, and epithelium. Cleavage of protease-activated receptors such as PAR2 may contribute to some of these activities, although other studies document PAR2-independent tryptase activation of mesenchymal cells.[67] In aggregate, these effects suggest an important role for tryptase in matrix remodeling. A further contribution to the inflammatory milieu is suggested by the capacity of tryptase to promote neutrophil and eosinophil recruitment and to cleave C3, C4, and C5 to generate anaphylatoxins.[68-70] Interestingly, tryptase can potentially suppress inflammation by cleaving IgE and IL-6.[71,72]

**Chymase.** Chymase, a chymotrypsin-like neutral protease, is found in the $MC_{TC}$ subset of human mast cells, packaged within the same granules as tryptase. Like tryptase, chymase can cleave matrix components and activate stromelysin, although it can also activate collagenase directly, suggesting a role in matrix remodeling.[73] Chymase can activate angiotensin I, leading to angiotensin-converting enzyme (ACE)–independent activation of the potent vasoconstrictor angiotensin II.[74] Chymase can also affect cytokine function, with the capacity to cleave pro-IL-1β to generate active cytokine and to inactivate pro-inflammatory cytokines such as IL-6 and TNF, as well as "alarmins," including heat shock protein 70 and IL-33.[75]

**β-Hexosaminidase.** β-Hexosaminidase is an enzyme found in lysosomes from many cell types. In mast cells it is abundant in secretory granules, where it is released into the surrounding environment during degranulation. Recent studies have found that this enzyme is capable of degrading bacterial cell peptidoglycan, and release by mast cells plays an important role in the defense against experimental staphylococcal infection in mice.[76]

**Vasoactive Amines.** Human mast cells are able to synthesize and store the biogenic amines histamine and serotonin, which are implicated in instances of vascular leak.[77] Histamine, which is by far more abundant than serotinin, is a vasoactive amine found in both $MC_T$ and $MC_{TC}$ mast cells, although it is not unique to this lineage. Histamine is involved in the wheal-and-flare response to cutaneous allergen challenge via augmented vascular permeability, transendothelial vesicular transport, and neurogenic vasodilation. These effects are mediated principally via the H1 receptor. Three other histamine surface receptors, H2, H3, and H4, are distributed widely on immune and nonimmune lineages, with effects as diverse as gastric acid secretion, Langerhans cell migration, and B cell proliferation.[78] Another important mechanism underlying mast cell–induced vascular leak is heparin-mediated bradykinin production (see the next section).

**Heparin and Chondroitin Sulfate E.** Heparin and chondroitin sulfate E are large proteoglycans that enable the ordered packing of mediators within human mast cell granules.[79,80] Negatively charged carbohydrate side chains complex tightly with positively charged proteins, allowing very high concentrations of β tryptase and other proteases. Heparin, which is produced exclusively by mast cells, facilitates the activity of tryptase by making possible proteolytic self-activation within the granule and stabilizing the active tetrameric form of this enzyme. Heparin also has a wide range of effects beyond the mast cell. It is potently angiogenic. Heparin binding activates antithrombin III, providing the basis for use as an anticoagulant, while inhibiting chemokines and both classical and alternative pathways of complement activation, as well as the function of Treg

cells.[81,82] The physiologic role of these extra-cellular activities is uncertain. Of more evident in vivo relevance is that the negatively charged surface of heparin enables activation of factor XII. This zymogen then activates kallikrein, an enzyme that in turn cleaves high-molecular-weight kininogen to generate bradykinin, a potent mediator of vascular leak. This mechanism contributes to the antihistamine-resistant edema observed in patients with hereditary angioedema from lack of C1 esterase inhibitor, an inhibitor of activated factor XII and kallikrein.[83]

**Pre-Formed Cytokines and Chemokines.** Mast cells are able to store certain mediators in their granules for rapid release. The first of these mediators to be documented was TNF.[84] In the mouse, this pool of TNF is implicated in the rapid recruitment of neutrophils to the peritoneum during peritonitis.[42,85] Exocytosed granules appear to release TNF gradually into the environment, enhancing the immunostimulatory effect of the cytokine as TNF-containing granules reach draining lymph nodes, helping to promote development of the mature immune response.[86-88] Other cytokines that may be stored in granules include IL-4, IL-16, basic fibroblast growth factor (bFGF), and vascular endothelial growth factor (VEGF). Stored chemokines include the neutrophil chemoattractants CXCL1 and CXCL2.[89]

### Newly Synthesized Mediators: Lipid Mediators, Cytokines, Chemokines, and Growth Factors

Beyond pre-formed mediators stored within granules, activated mast cells elaborate a range of mediators that are generated de novo. These mediators are released minutes to hours after stimulation, broadening and extending the impact of activated mast cells on surrounding tissues.

**Lipid Mediators.** Within minutes of activation, mast cells begin to release metabolites of membrane phospholipids. This process is rapid because the relevant enzymes, beginning with phospholipase A2, which is responsible for harvesting phospholipids from the outer leaflet of the nuclear membrane, are already present in the cytoplasm and need only to be activated through signals mediated by calcium flux and the phosphorylation of intra-cellular messengers. The hallmark prostaglandin of human mast cells is prostaglandin $D_2$ ($PGD_2$), which induces bronchoconstriction, vascular leak, and neutrophil recruitment. Smaller amounts of other prostaglandins, as well as thromboxane, are also made. Mast cell–derived leukotrienes (LTs) have similar but generally more potent activity. $LTC_4$ (the major LT species generated by human mast cells), together with its metabolites $LTD_4$ and $LTE_4$, serve as potent inducers of vascular leak. Smaller amounts of the chemotaxins $LTB_4$ and platelet-activating factor (PAF) are also generated. The particular profile of lipid mediators produced by mast cells can change with local environmental signals and the resulting state of differentiation. Thus mast cells from skin generate $PGD_2$ in excess of $LTC_4$, whereas both species are elaborated in roughly equal proportion by mast cells isolated from lung and osteoarthritic synovium.[90]

**Cytokines, Chemokines, and Growth Factors.** Within hours of activation, mast cells begin to elaborate newly synthesized mediators as the end result of induced gene transcription and translation. The range of such mediators is broad (see Figure 15-3). They include the canonical pro-inflammatory mediators TNF, IL-1, and IL-6; the Th2 cytokines IL-4, IL-5, IL-10, and IL-13; the "alarmin" IL-33; chemotactic factors including IL-8, macrophage inflammatory protein (MIP)-1α, CXCR1, CXCR2, and RANTES (regulation upon activation normal T cell expressed and presumably excreted); and growth factors for fibroblasts, blood vessels, and other cells such as bFGF, VEGF, and platelet-derived growth factor (PDGF).[91] IL-17 is detected in tissue mast cells and can be generated by mast cells stimulated in culture.[92-94] As noted earlier, some of these cytokines may also be stored pre-formed in granules for rapid release. The panel of mediators generated depends on the state of differentiation, as well as the activating signal, and may occur in the absence of degranulation.

## ROLE OF MAST CELLS IN HEALTH AND DISEASE

The understanding of the role of mast cells in health and disease has been aided greatly by the availability of mice that lack mast cells entirely or are deficient in mast cell–specific products such as heparin or granule proteases. These mice are viable, excluding an obligate role for mast cells in the structure and function of most tissues. Yet when they are under physiologic stress, such as that imposed by experimental models of disease, multiple differences from wild-type mice become evident. In many cases, these abnormalities may be corrected by engraftment with cultured mast cells,[95] directly implicating mast cells in a remarkably broad range of disease processes (Table 15-1). The extrapolation of such experiments to human disease is limited by multiple factors. Most evidently, mice are not humans, and the experimental systems used typically model at best only certain aspects of the corresponding human condition. Further, many of these mice exhibit "off-target" phenotypes outside of the mast cell lineage, complicating interpretation of the data, especially when results in one mast cell–deficient mouse strain diverge from those observed in another. These discrepancies have occasioned considerable controversy in the mast cell–related literature.[96,97] However, together with in vitro experiments using human mast cells and careful study of individuals in different states of health and disease, animal experiments have contributed greatly to the understanding of mast cell physiology and pathophysiology.

### Mast Cells in Allergic Disease: Anaphylaxis, Allergic Disease, and Asthma

Mast cells are the primary mediator of IgE-mediated systemic anaphylaxis. This phenomenon is demonstrated in mast cell–deficient mice, in which resistance to anaphylaxis may be restored by engraftment with mast cells.[98] In humans, participation of mast cells in anaphylaxis has been documented through the detection of elevated serum levels of β tryptase, a specific marker of mast cell degranulation.[63] Of note, anaphylaxis may be mediated by IgG, a context in which mast cells play only a partial role, while neutrophils assume primacy.[99] Mast cells accumulate in atopic mucosal tissues where they degranulate upon exposure to antigen and contribute prominently to tissue edema and the overproduction of mucus.[100] Mast cells also accumulate in the asthmatic airway, including within the smooth muscle

**TABLE 15-1** Participation of Mast Cells in Murine Models of Disease (Partial List)

| Beneficial to Host | Harmful to Host |
|---|---|
| Angiogenesis | Anaphylaxis* |
| Anxiety control | Arthritis* |
| Bacterial cystitis | Aortic aneurysm* |
| Bacterial peritonitis* | Asthma* |
| Bone remodeling | Atherosclerosis* |
| Brain trauma | Atopic dermatitis |
| Dengue fever | Atrial fibrillation |
| Dermatitis* | Autoinflammatory disease |
| Envenomation* | Bacterial cystitis |
| Glomerulonephritis* | Burn |
| Graft tolerance* | Bullous pemphigoid* |
| Intestinal epithelial barrier* | Cardiac fibrosis |
| Lung infection, bacterial* | Cardiomyopathy |
| Lung infection, viral* | Chronic obstructive pulmonary disease |
| Parasites, intestine* | Colitis |
| Parasites, muscle | Colon polyps |
| Parasites, skin | Dermatitis, irritant* |
| Peptic ulcer disease | Dermatitis, sunburn |
| Thromboembolism | Gastritis |
| Tumor suppression* | Glomerulonephritis* |
| Wound healing* | Gout |
| | Immune complex peritonitis* |
| | Ischemia-reperfusion injury |
| | Kidney injury* |
| | Lung fibrosis |
| | Malaria |
| | Multiple sclerosis* |
| | Myositis* |
| | Neurogenic inflammation* |
| | Obesity* |
| | Peritonitis, irritant* |
| | Peritoneal adhesions |
| | Pneumonitis |
| | Renal fibrosis* |
| | Scleroderma |
| | Sepsis* |
| | Tumor angiogenesis |

Mast cells are implicated in these processes by virtue of phenotypic abnormalities in mast cell–deficient mice or in mice lacking mast cell-specific mediators. The asterisk (*) indicates that the phenotype has been shown to be reversible by engraftment with cultured mast cells, providing more direct evidence for a role for this lineage.

lining the airways, and have been implicated by human and animal data in airway hyper-reactivity and mucosal changes.

## Mast Cells in Nonallergic Inflammation

### Pathogen Defense: Mast Cells as Sentinels of Innate Immunity

The involvement of mast cells in atopic disease is clear but does not explain their remarkable evolutionary conservation.[101] Rather, mast cells must somehow contribute to the survival of the organism. The most probable mechanism by which mast cells convey a survival advantage is in the defense against infection. This role is suggested by the localization of mast cells near epithelial surfaces, around blood vessels, and in other locations of potential invasion by pathogens.

Mast cells are competent defensive cells against bacteria. They express TLRs and other receptors against bacterial antigens, and upon activation are able to phagocytose bacteria and generate anti-microbial molecules such as cathelicidin.[102,103] However, given their relatively small numbers, the most important function of mast cells in immune defense is likely as sentinels, monitoring for early traces of infection and rapidly mobilizing neutrophils and other inflammatory cells when needed. Such a role has been clearly demonstrated in mouse models of bacterial peritonitis, in which mast cell–deficient animals exhibit a high mortality. This susceptibility correlates with delayed recruitment of neutrophils via TNF and leukotrienes; both neutrophil influx and survival may be restored by correction of the mast cell deficit, although in the case of severe infection, mast cell TNF may actually contribute to mortality.[85,104-106] Clearance of bacteria from the lungs is delayed in mast cell–deficient mice and can be similarly restored by exogenous mast cells.[85] Analogous observations have been made in other models of bacterial infection. Thus mast cells likely play an important role in the defense of the host against bacterial infection.

Mast cells are also implicated in the defense against parasites. Mast cell–deficient animals exhibit abnormal clearance of multiple parasites from the gut and skin, in a manner promoted by IgE.[107,108] The mechanism of this defense remains uncertain but may include direct attack upon pathogens, recruitment of inflammatory lineages such as neutrophils and eosinophils, and lysis of tight junctions in the mucosal lining to facilitate the expulsion of helminths.[107,109,110] More limited data implicate mast cells in the defense against viruses, including dengue, vaccinia, and cytomegalovirus. The role of mast cells in this setting includes recruitment of CD8 T cells and other cytotoxic lineages, as well as production of type I IFNs to help neighboring cells resist infection.

### Mast Cells and the Adaptive Immune Response

In addition to recruiting innate effector cells, mast cells mobilize T and B lymphocytes, the adaptive arm of the immune system.[91] Mast cells may express major histocompatibility complex (MHC) II, as well as co-stimulatory molecules such as CD80 and CD86, rendering them effective antigen-presenting cells for CD4 T cells. Mast cells can also

mobilize and potentiate CD8 T cell responses.[111] They can migrate from peripheral tissues to lymph nodes carrying antigen and contribute to the recruitment of T cells to lymph nodes via mediators including MIP-1β and TNF.[8,86,112] Indeed, infection-induced lymph node hyperplasia is abrogated in the absence of mast cells. Further, mast cells can recruit CD4 and CD8 effector T cells to peripheral tissues via $LTB_4$, among other mediators.[113-115] Finally, mast cells contribute to the migration of cutaneous Langerhans cells and other dendritic cells to lymph nodes via mediators including histamine.[116-118] By means of the inducible expression of CD40L and cytokines, mast cells stimulate B cells and induce class switching to IgA or IgE.[119,120] The physiologic importance of these effects will vary with circumstances. For example, under some conditions, delayed-type hypersensitivity responses in skin are dependent on mast cells, whereas under other conditions, mast cells play no role.[91] The potential importance of the mast cell in adaptive immunity is highlighted by the recent demonstration that mast cell activators are effective vaccine adjuvants.[87]

### Neurogenic Inflammation

In addition to their perivascular localization, mast cells cluster near and sometimes within peripheral nerves. A discrete function for them in these locations has not yet been defined, although the potential for bidirectional neuroimmune interaction is clear. Mast cell mediators such as histamine can directly activate neurons, whereas mast cells residing near stimulated neurons can be induced to degranulate.[121] Indeed, vascular leak and neutrophil infiltration arising from infiltration of skin with the neurogenic mediator substance P are mediated by mast cells.[122,123] Thus neurons might recruit mast cells as local effectors of neurogenic inflammation.

### Autoimmune Disease

Reconstitution experiments in mast cell–deficient mice have implicated mast cells in a variety of pathologic conditions (see Table 15-1), including murine models of autoimmune diseases such as bullous pemphigoid, multiple sclerosis, scleroderma, and inflammatory arthritis. In mice with pemphigoid, mast cells that are triggered via IgG antibodies against a hemidesmosomal antigen recruit neutrophils, which are responsible for blister formation.[44] The role of mast cells in murine experimental autoimmune encephalomyelitis (EAE) is more complex. Although the resistance of mast cell–deficient $W/W^v$ mice to EAE corrects with mast cell engraftment, these cells fail to repopulate the brain and spinal cord, indicating that mast cells are not obligate local effector cells in this model.[124,125] One mechanism for this activity appears to be the promotion of the adaptive immune response, because mast cell engraftment into $W/W^v$ animals improves T cell responses to immunization with the inciting myelin antigen.[126,127] The contribution of mast cells to human scleroderma remains unknown, although they are recognized to express TGF-β in sclerodermatous skin and to interact closely with local lymphocytes and fibroblasts, even to the point of gap junction formation and therefore cytoplasmic continuity with the latter cells.[128,129] Humans with polymyositis, but not dermatomyositis, exhibit increased density of mast cells in inflamed muscle; a similar phenotype is noted in dermatomyositis skin.[130,131] Murine studies suggest that these cells may play a role in disease pathogenesis, because experimental myositis is attenuated in mast cell–deficient animals, a defect that corrects partially with mast cell engraftment.[131] The participation of mast cells in arthritis is discussed in detail later.

## Mast Cells as Anti-Inflammatory Cells

Within the past decade, it has become evident that mast cells may also help moderate the immune response. One mechanism for this effect is degradation of pro-inflammatory mediators. Mast cell proteases may cleave and inactivate the cytokines IL-5, IL-6, IL-13, IL-33, and TNF, as well as endothelin-1 and the anaphylatoxin C3a.[69,75,132-134] Proteases also degrade tissue-derived danger signals, including heat shock protein 70.[75] The importance of this anti-inflammatory activity has been demonstrated in a murine sepsis model, where mast cells reduced mortality by restraining excess inflammation in a protease-dependent manner.[134]

More broadly, mast cells can produce mediators such as IL-10 that have immunosuppressive activity, and even otherwise pro-inflammatory mediators such as TNF and granulocyte-macrophage colony-stimulating factor (GM-CSF) can be immunosuppressive under appropriate circumstances.[135,136] Thus mast cells promote immunologic tolerance to skin grafts and limit tissue inflammation related to ultraviolet light injury.[72,136-138] Data suggest a role for mast cell–produced IL-2 in the promotion of Treg responses that limit experimental dermatitis, as well as in the development of IL-10–producing regulatory B cells.[139,140] Mast cells may play a permissive role in the immunosuppressive activity of murine myeloid-derived suppressor cells, an activity that may be beneficial or harmful to the host.[141,142]

## Mast Cells and Connective Tissue

### Wound Healing and Tissue Fibrosis

Mast cells have long been noted to accumulate at the borders of healing wounds. In healthy human subjects undergoing experimental wounding and recurrent biopsies, mast cell numbers increase sixfold by day 10 after the initial incision. These mast cells localize preferentially to fibrotic areas of the wound and strongly express IL-4, a cytokine capable of inducing fibroblast proliferation and collagen synthesis.[143] In vitro studies confirm the stimulatory effects of mast cells on fibroblast growth[144]; candidate fibroblast mitogens in addition to IL-4 include tryptase, histamine, $LTC_4$, and bFGF. Indeed, $W/W^v$ animals exhibit delayed contracture and healing of skin wounds in a manner reparable by local engraftment with cultured mast cells, although other mast cell–deficient mice exhibit no defect in wound healing.[145,146]

Mast cells also accumulate in sites of pathologic fibrosis, including the skin and lungs of patients with scleroderma. Because experimental skin fibrosis proceeds in mast cell–deficient mice with few if any differences in intensity or kinetics, it is unlikely that mast cells are an obligate effector

lineage in human scleroderma, although they may contribute to disease progression.

### Bone

Mast cells are also implicated in the remodeling of bone. Mast cells accumulate in sites of healing fracture, and under normal circumstances, they may contribute to normal bone turnover.[147,148] However, mast cells accumulate in osteoporotic bone, and systemic osteoporosis is a known complication of systemic mastocytosis.[149,150] Heparin is one potentially important mediator of bone loss because it directly promotes differentiation and activation of osteoclasts.[151] Mast cell products such as IL-1, TNF, and MIP-1α have similar activity.

### Angiogenesis

Another potentially important activity of mast cells on the stroma is the promotion of angiogenesis. Mast cells are not required for the development of the normal vasculature, as is evident in the viability of mast cell–deficient mice. However, mast cells cluster at sites of early blood vessel growth in tumors and contribute appreciably to physiologic angiogenesis under certain experimental conditions.[152,153] Heparin was the first proangiogenic mast cell mediator identified; bFGF and VEGF are other potent stimulators of endothelial migration and proliferation.

## Mast Cells in Arthritis

The normal synovium is populated by a limited number of mast cells. These cells are not found in the immediate lining layer but rather reside in the synovial sublining near blood vessels and nerves, constituting almost 3% of cells within 70 μM of the synovial lumen.[154] In both mice and humans, their phenotype is principally $MC_{TC}$, similar to mast cells found in most other connective tissue sites.[23,155] The severalfold increased density of mast cells in the immediate vicinity of the synovial lining, compared with more distant connective tissue, supports the hypothesis that mast cells contribute to immune surveillance of the articular cavity.[23] Extrapolating from the activity of mast cells near other vulnerable body cavities, such as the peritoneum, it is likely that synovial mast cells help monitor the joint for early evidence of infection.

In the presence of inflammatory arthritis, the population of synovial mast cells expands remarkably (Figure 15-4). More than two-thirds of synovial specimens from patients with rheumatoid arthritis (RA) exhibit abnormal numbers of mast cells, averaging in excess of tenfold above normal.[156] Consistent with these histologic findings, synovial fluid from rheumatoid joints contains appreciable quantities of histamine and tryptase.[157,158] Unlike the normal joint, in the RA joint both subtypes of mast cells are present in roughly equal numbers, with $MC_T$ cells located nearer to the pannus and infiltrating leukocytes, whereas $MC_{TC}$ cells cluster in deeper, more fibrotic areas of the synovium.[23] Mast cells have been noted near the junction of pannus and cartilage.[159] Rare mast cells are also identified in synovial fluid.[160] The absence of mitotic figures and of staining for the proliferation antigen Ki-67 suggests that they arise not from local replication but rather by recruitment of circulating progenitors.[161] Although the signals driving this recruitment are unknown, inflammatory cytokines such as TNF enhance expression of the mast cell chemotactic and survival factor SCF on synovial fibroblasts, suggesting one mechanism.[162] Indeed, degree of inflammation is the best predictor of the number of mast cells within the joint.[156,163,164] Incompletely identified factors in RA synovial fluid can potently promote mast cell differentiation and growth.[165]

Hyperplasia of the mast cell population is not specific for RA but is observed in a wide range of inflammatory joint disorders (Table 15-2). Expansion is also noted in osteoarthritis (OA), often to densities observed in RA.[166] The levels of histamine and tryptase in OA synovial fluid are also comparable. Interestingly, unlike in RA, the expansion in OA results from an increase in numbers of $MC_T$ mast cells, the subtype generally associated with T cells and inflammation.[23,167]

Studies of human synovial mast cells confirm that they can be activated via pathways relevant to arthritis biology, including complement, Fc receptors, and TLR ligands.[41,168,169] Mast cells are also a potential source of citrullinated

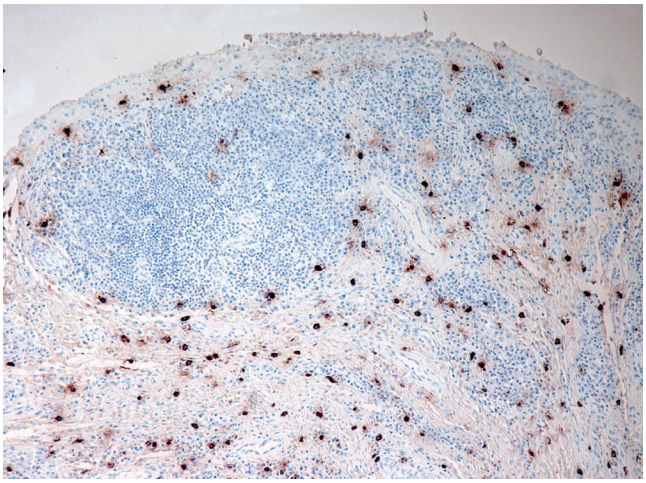

**Figure 15-4** Mast cells in the rheumatoid synovium. Stained red by an antibody against tryptase, mast cells are abundant in this synovial biopsy from a patient with chronic rheumatoid arthritis. Note the proliferation of mast cells in the synovial sublining. *(From Nigrovic PA, Lee DM: Synovial mast cells: role in acute and chronic arthritis.* Immunol Rev *217:19–37, 2007.)*

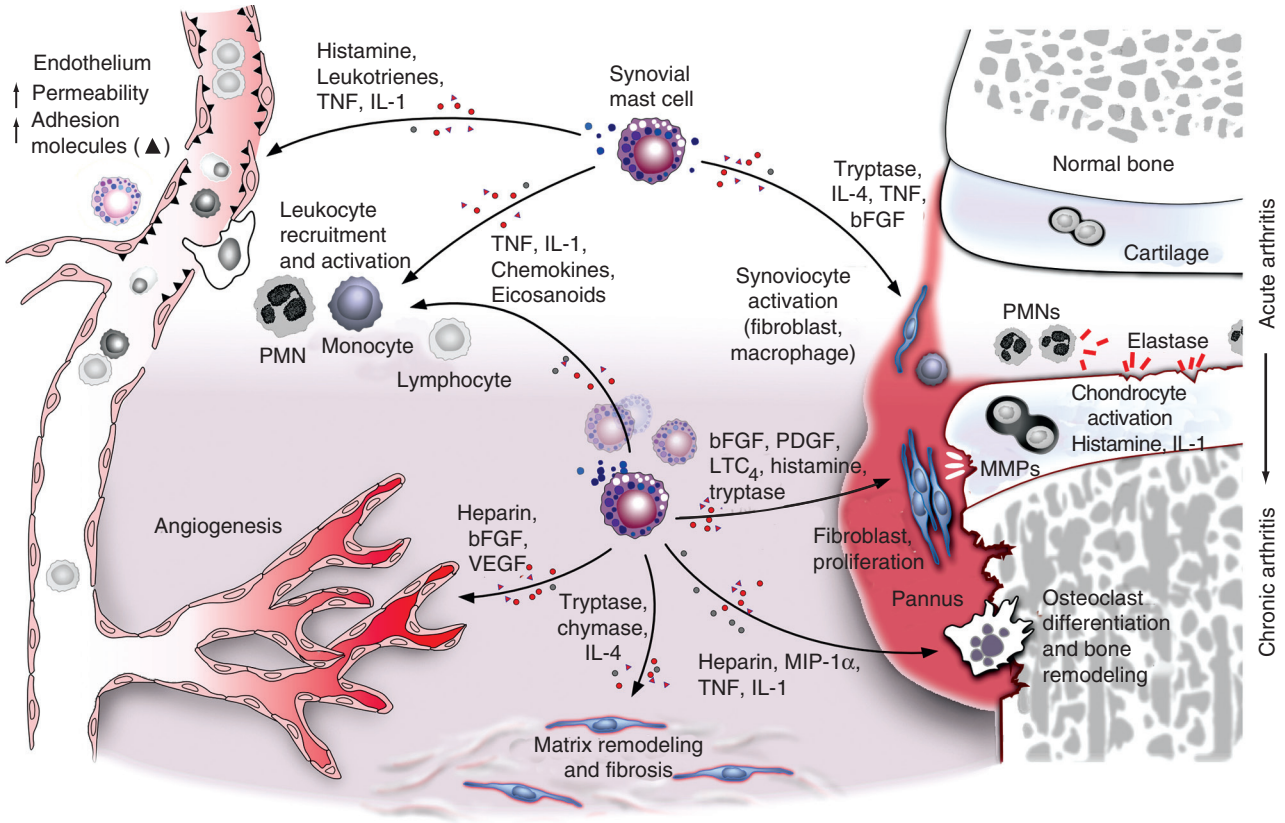

**Figure 15-5** Potential roles of mast cells in acute and chronic arthritis. In the acute phase of joint inflammation, mast cells may contribute to initiation of arthritis by inducing vascular permeability, recruiting and activating circulating leukocytes, and stimulating local fibroblasts and macrophages. In established arthritis, these activities may be joined by effects on the stroma, including the promotion of pannus formation, angiogenesis, fibrosis, and injury to cartilage and bone. Potential anti-inflammatory effects of mast cells are not depicted. The mediators listed are representative and do not represent a complete list. bFGF, Basic fibroblast growth factor; IL, interleukin; $LTC_4$, leukotriene $C_4$; MIP-1α, macrophage inflammatory protein-1α; MMP, matrix metalloproteinase; PDGF, platelet-derived growth factor; PMN, polymorphonuclear neutrophil; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor. *(From Nigrovic PA, Lee DM: Synovial mast cells: role in acute and chronic arthritis,* Immunol Rev *217:19–37, 2007.)*

autoantigens implicated in RA, although their relative importance in this context is unknown.[170]

## Mast Cells in Acute Arthritis: Insights from Animal Models

Experimental work in mice has shed light on the role of mast cells in inflammatory arthritis. Several mast cell–deficient strains demonstrate striking resistance to arthritis induced by IgG autoantibodies, a defect that may be repaired by engraftment with cultured mast cells expressing receptors for IgG and C5a.[39,45,171-173] A number of mechanisms contribute to this arthritogenic activity. First, mast cells induce vascular permeability, facilitating entry of autoantibodies into the joint.[174,175] Second, mast cells release proinflammatory mediators including IL-1 that help establish inflammation, presumably via effects on endothelium and other local populations such as macrophages and fibroblasts.[45,173] These actions appear to be most critical at the initiation of disease, constituting a "jump start" for acute inflammation within the joint. This function is in line with the activity of mast cells in other models of IgG-mediated disease, such as IgG-mediated immune complex peritonitis, murine bullous pemphigoid, and anaphylaxis. In each of these models, mast cells resident in tissue for the purpose of immune defense become co-opted by autoantibodies to initiate inflammatory disease (Figure 15-5, *top*). Mast cells have also been implicated in monosodium urate crystal sensing and cytokine production in experimental gout.[54]

Of note, not all mice lacking mast cells are resistant to experimental arthritis.[45,176,177] The basis for this discordance is not fully understood but likely reflects factors that include the intensity of the arthritogenic stimulus and the susceptibility of the background strain. This suggestion is reinforced by studies in mice lacking specific mast cell proteases, where partial protection from arthritis is evident, but only in the context of a submaximal arthritis stimulus.[67,178] These data suggest that mast cells represent one potential contributor to joint inflammation but that their importance will vary with context.

## Mast Cells in Chronic Arthritis

In contrast to the acute phase of joint inflammation, the role of mast cells in established arthritis is poorly understood. The sheer numbers of these cells in arthritic synovium implies a substantial role. Taking into account the spectrum of mast cell activity elsewhere, it is likely that mast cells

participate both in the inflammatory process and in the mesenchymal response (Figure 15-5, *bottom*).[166]

An ongoing contribution of mast cells to inflammatory arthritis is suggested by several observations. First, as noted, prominent among infiltrating synovial mast cells are $MC_T$ cells, typically associated elsewhere with the elaboration of cytokines such as IL-6 with documented pathogenic activity in RA. Immunofluorescence staining has identified TNF and IL-17 in mast cells from inflamed synovium,[7,93,179] and the elaboration of other pro-inflammatory mediators is probable. Second, mast cells from RA but not OA synovium express the receptor for the anaphylatoxin C5a, a mediator readily documented in synovial fluid.[168] Immune complexes within RA joints represent a likely pathway to activation of synovial mast cells.[180] Indeed, ultrastructural data support ongoing degranulation of mast cells in the RA synovium.[167] Finally, studies of c-Kit inhibitors in murine and human arthritis suggest efficacy, although it remains unclear whether these agents functionally antagonize tissue mast cells and whether such antagonism explains their efficacy, because these agents have an impact on multiple kinases and affect a broad range of lineages.[181,182]

The effect of mast cells on the established inflammatory synovial infiltrate is difficult to predict. As in acute arthritis, activated mast cells may promote the recruitment and activation of leukocytes. Alternately, protease cleavage of inflammatory mediators and the elaboration of cytokines such as IL-10 and TGF-β could suppress inflammation, potentially by promoting Treg function, as has been observed in tolerance of skin grafts in mice.[137]

Mast cells likely modulate the stromal response to inflammation. Expansion and activation of synovial fibroblasts is a key pathogenic process within RA, and the capacity of mast cells to promote such changes is well established. Through interaction with osteoclasts, mast cells could promote both focal erosions and periarticular osteopenia. Mast cell tryptase not only promotes inflammation but can contribute directly to joint injury by activating synovial fibroblasts to produce chemokines and by cleaving substrates such as cartilage aggregan, both directly and through proteolytic activation of matrix metalloproteinases.[67,178,183-185] Finally, by producing proangiogenic mediators, mast cells may enable growth of the vascular supply required for the profound expansion of the thin synovial layer into thick pannus. Confirmation of these roles awaits further experimental data.

## Therapeutic Potential of Mast Cell Antagonism in Rheumatic Disease

The broad involvement of mast cells in health and disease suggests that targeting this lineage could have potential therapeutic value. Multiple strategies for blocking mast cell activity are under active consideration.[186] In the context of atopic disease, targeting IgE and its receptor FcεRI offers the appealing prospect of antagonizing a pathway of direct disease relevance while retaining most protective mast cell functions. In rheumatic diseases, however, such specificity will be more difficult to achieve because the pathways by which mast cells are engaged, and their downstream effector responses, are typically relevant for immune defense and are shared by multiple hematopoietic lineages.

### Mast Cell Protease Inhibition

Mast cell proteases make up the bulk of the protein content of these cells and are in many cases largely or entirely specific to this lineage, as previously described. Targeting these proteins therefore offers a pathway to selective mast cell antagonism, in particular because mast cell proteases are implicated directly in arthritis pathogenesis, both as pro-inflammatory factors and as mediators of tissue injury.[67,178,185] Protease inhibitors have been generated but are not currently in active clinical development for arthritis.[186]

### SCF/c-Kit Antagonism

Given the critical importance of the SCF/c-Kit axis for the development and survival of mast cells, attention has focused on the potential of kinase inhibitors as mast cell antagonists. Although no inhibitors are fully specific to c-Kit, the tyrosine kinase inhibitors imatinib and mastinib and the downstream protein kinase C inhibitor midostaurine exhibit relative selectivity for c-Kit and have clinical utility in some cases of systemic mastocytosis.[187] These treatments may be complicated by neutropenia and thrombocytopenia, reflecting the importance of c-Kit in other hematopoietic lineages. Imatinib is effective in murine arthritis, in doses that affect in vitro mast cell activation; similarly, imatinib treatment of human synovial cultures induces apoptosis of mast cells and limits cytokine production.[7,93,181] However, the action of this agent on multiple synovial lineages obscures the role of mast cell targeting in these results, even in vitro.[181] Interestingly, imatinib is less effective at antagonizing c-Kit stimulation from immobilized SCF, as between tissue-resident mast cells and their adjacent fibroblasts.[17] Further, both in vitro and in vivo data suggest that c-Kit signaling can be at least partially replaced by other survival signals from the inflamed environment, such as IL-33.[10,188] Together, these results suggest that c-Kit blockade is unlikely to represent a mast cell–specific therapeutic approach, although effects on mast cells may certainly contribute to the clinical improvement suggested by series of patients with rheumatic diseases, including RA, treated with kinase inhibitors.[182,189-191]

### Signaling Pathways

Mast cells share pathways of intra-cellular signaling with other cells, but disproportionate use of individual pathways could offer the potential for pharmacologic specificity. Examples of such pathways include the delta isoform of phosphoinositide 3 kinase (PI3Kδ) and Ras guanine nucleotide-releasing protein-4 (RasGRP4). PI3Kδ is involved in intra-cellular signaling in mast cells, including downstream of c-Kit, and mice lacking this receptor exhibit a partial deficiency of mast cells in some tissues and a striking reduction of IgE-mediated signaling and anaphylaxis.[192,193] Mice lacking RasGRP4, a guanine nuclear exchange factor expressed principally in mast cells, exhibit impaired mediator production by this lineage and impaired inflammation in models of colitis and arthritis.[194,195] Antagonism of targets such as these could hold the promise of limiting the contribution of mast cells to human disease,

although the clinical efficacy and side effect profile of such blockade will depend greatly on the availability of redundant pathways within human mast cells and the expression of these targets in other lineages.

## CONCLUSION

Mast cells are potent immune cells characterized by phenotypic diversity and an extremely broad range of functions in health and disease. In addition to mediating atopic disease, mast cells represent important sentinels against pathogen invasion. Under certain conditions it is likely that they also participate in the control of the immune response and the remodeling of tissue matrix. Aberrant activation of mast cells by autoantibodies and potentially other signals has been identified in a range of inflammatory diseases, including arthritis. Such activation may represent a key pathologic step in the development of tissue inflammation and injury and could present an interesting target for the development of anti-inflammatory therapies.

CHAPTER 16

# Platelets

Eric Boilard • Peter A. Nigrovic

**KEY POINTS**

- Platelets are small subcellular fragments that circulate in blood, where they promote hemostasis.
- Platelets express receptors and a multitude of mediators recognized as being active in inflammation.
- Inhibition of platelet functions generally involves blockade of G protein–coupled receptor soluble agonists (e.g., thromboxane, thrombin, and adenosine diphosphate). However, platelet immunoreceptor tyrosine-based activation motif signaling at the site of inflammation is also implicated.
- Platelets likely contribute to inflammation in rheumatic diseases, including rheumatoid arthritis and systemic lupus erythematosus.
- Specific blockade of platelet pro-inflammatory functions could represent a new approach to treatment of the rheumatic diseases and their associated cardiovascular risks.

Platelets patrol the vasculature to promote hemostasis. In blood, platelets represent the second most abundant cellular lineage after the red blood cell, outnumbering leukocytes by several orders of magnitude. When damage to the vasculature occurs, platelets quickly respond to prevent blood loss. However, in addition to their recognized role in thrombosis, platelets are emerging as important participants in the separation of blood and lymphatic systems, in maintenance of vasculature integrity in inflammation, and in immune responses. Accumulating evidence suggests that platelets and their bioactive mediators are important contributors to the pathogenesis of rheumatic diseases.

## PLATELET STRUCTURE

Platelets are small subcellular fragments that circulate in blood. In humans, normal platelet counts range between $150 \times 10^6$/mL and $450 \times 10^6$/mL, making them the second most abundant cell lineage present in blood after erythrocytes. Structurally, resting platelets resemble irregular discs that are 2 to 5 μm in diameter and 0.5 μm thick, with a volume of 6 to 10 femtoliters. In comparison, lymphocytes and neutrophils have a volume of 218 and 330 femtoliters, respectively.[1,2] Because of their small size and discoid shape, platelets are continuously pushed by the blood flow toward the edge of blood vessels, positioning them optimally to recognize endothelial injury. Thus because of their structure and abundance in the blood, platelets are positioned to fulfill their hemostatic function: the maintenance of vascular integrity.[3]

The cytoskeleton is necessary for maintaining the platelet's discoid shape.[4] A spectrin-based cytoskeleton is associated with the cytoplasmic side of the plasma membrane, microtubule coils form along the circumference of the cell, and 2000 to 5000 linear polymers of actin, the most abundant protein expressed by platelets, fill the cytoplasm.[5-7] These cytoskeletal components maintain the platelet's structure in the setting of high fluid shear forces and also enable conformational changes with activation to form finger-like filopodia and pseudopods.[8] Under these conditions, the platelet structure is remodeled dramatically, changing from a disk to spiny sphere.

The resting platelet plasma membrane is composed of phospholipids and, on electron microscopy, it appears smooth with a fine corrugated surface, resembling the surface of the brain.[9,10] The surface membrane contains channels and sinuous invaginations called the open canicular system (OCS).[11] The OCS increases the platelet surface area in direct contact with the extra-cellular milieu. Plasma components such as serotonin and fibrinogen are imported into platelets through this system, and the OCS serves as a conduit for the release of mediators stored within the platelet.[12,13] The channels that constitute the OCS are also a source of membrane necessary for the profound morphologic changes, such as the formation of filopodia and spreading that occur rapidly when platelets are activated, increasing their exposed surface by 420%.[14] Adherent platelets have been observed to trail long (250 μm) tendrils into the blood vessel lumen, further increasing their contact surface and helping them to interact with circulating leukocytes.[15]

The platelet cytoplasm includes numerous small organelles that include three main types of secretory granules: the α-granules, dense bodies (δ granules), and lysosomes (Table 16-1). The α-granules are the most abundant organelle in platelets (40 to 80 per platelet).[16,17] They are round or oval, have a diameter of 200 to 500 nm, and contain proteins in their lumens or membrane, including von Willebrand factor (vWF), P-selectin, coagulation factor V, thrombospondin, fibrinogen, platelet factor-4 (also known as CXCL4), and growth factors such as platelet-derived growth factor (PDGF) and tumor growth factor-β (TGF-β).[18] Dense bodies are smaller than α-granules, are fewer in number (4 to 8 per platelet), and are rich in calcium, magnesium, adenosine diphosphate (ADP), adenosine triphosphate (ATP), serotonin, and histamine.[19,20] Calcium and

**TABLE 16-1** Platelet Components Implicated in the Inflammatory Response

| | Platelet Component | Actions |
|---|---|---|
| Surface molecules | P-selectin (CD62P), PECAM (CD31), GPIbα | Adhesive targets for leukocytes |
| | PAF, ROS | Neutrophil activation |
| | CD154 (CD40 ligand) | Agonist for endothelial cells |
| Soluble factors | Serotonin, histamine | Regulators of vascular permeability |
| | β-Thromboglobulin, PF4 | Chemotaxis |
| | Acid hydrolases, ROS | Tissue destruction |
| | PDGF, TGF-β | Cellular mitogens, chemoattractant |
| End products of platelet procoagulant activity | Thrombin, fibrin | Promote leukocyte accumulation |

GPI, Glycosyl phosphatidylinositol; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; PECAM, platelet–endothelial cell adhesion molecule; PF4, platelet factor-4; ROS, reactive oxygen species; TGF, transforming growth factor.

serotonin are responsible for the opacity of dense bodies on electron microscopy. Platelets also usually bear approximately one lysosome (sometimes none and never more than three). These lysosomes may serve as an endosomal digestion compartment, but the importance of this function in hemostasis is unknown. Proteolysis can also take place in platelet proteasomes.[21] The proteasome is necessary for platelet function, because its pharmacological blockade by the proteasome inhibitor bortezomib (given to patients with multiple myeloma) inhibits platelet thrombotic activities and platelet production.[22,23] Platelets express residual fragments of Golgi complexes and functional mitochondria (4 to 7 per platelet), which are implicated in the production of energy and platelet activation.[21,24]

## PLATELET PRODUCTION

The great majority of the platelets will never be involved in any hemostatic process and will be eliminated at senescence through the reticuloendothelial system in the liver and spleen. Because of their relatively short life span in circulation (10 days), approximately 100 billion platelets must be produced every day in the human body. Platelets are not cells per se; they are fragments derived from megakaryocytes and, consequently, they are deprived of a nucleus.[25,26] The megakaryocyte arises from a master stem cell in the bone marrow under the control of thrombopoietin, a hormone produced in the liver and kidneys that promotes megakaryocyte maturation, number, and size and forestalls megakaryocyte apoptosis.[27,28] Thrombopoietin is a soluble, 80 to 90 kDa protein that acts through binding to its receptor, c-Mpl, which is expressed by megakaryocytes and platelets. The binding of thrombopoietin to platelets induces its catabolism. More thrombopoietin is thus available in persons with lower platelet counts, thereby driving megakaryocyte activity. Further, aging platelets directly induce thrombopoietin expression in hepatocytes because they are cleared through an interaction between desialyated platelet surface glycans and the hepatic asialyloglycoprotein receptor.[29]

Cytokines such as interleukin (IL)-1, IL-3, IL-6, IL-11, stem cell factor (also called Kit ligand) and granulocyte-macrophage colony-stimulating factor amplify megakaryocyte production.[30-32] Enhanced platelet production can be assessed by measurement of the mean platelet volume (MPV), a measure that is often part of a complete blood cell count (CBC). A larger average platelet size is seen when platelet production by megakaryocytes is increased, generally reflecting compensation for accelerated platelet destruction as seen in immune thrombocytopenic purpura (ITP), myeloproliferative diseases, and Bernard-Soulier syndrome.[33]

The mature megakaryocyte is a giant cell (50 to 100 μm in diameter) and is capable of endomitosis, meaning that it undergoes repeated cycles of DNA replication without cell division, leading to polyploidy, typically up to 16N (128N can be observed).[34] This amplification of DNA results in gene amplification and increases protein production, which is necessary for the generation of up to 5000 platelets per megakaryocyte. During platelet formation, long (millimeters in length) cytoplasmic extensions emanate from the megakaryocyte and protrude out of the bone marrow in the interior of vascular sinusoids. These extensions, called proplatelet processes, elongate through the action of microtubules, which also serve as a track for the transportation of membranes, organelles, and granules from the mother megakaryocyte distally into nascent proplatelets. Actin filaments participate in proplatelet branching. Cytoplasmic continuity between the mother megakaryocyte and nascent proplatelets also enables platelets to bear functional microRNA and messenger RNA, as well as the molecular machinery required to translate the latter efficiently into protein.[35,36]

Fragments from proplatelet processes are next released into the blood as either globular pre-platelets or as barbell-shaped proplatelets (Figure 16-1). These interconvertible forms generate platelets upon fission. Furthermore, individual human platelets can divide.[37] These observations suggest that platelet maturation continues in the circulation. Interestingly, megakaryocytes can migrate into the bloodstream, and evidence suggests that an appreciable proportion of platelets is generated by the megakaryocytes that have taken up residence in the lungs.[25,38]

## PLATELETS AND HEMOSTASIS

The sum of the processes by which the loss of blood is prevented is called hemostasis. Intravital microscopic analyses, performed as early as in 1882 by the Italian scientist Bizzozero, demonstrated that platelets could recognize a damaged blood vessel and form a plug.[1] Since then, the molecular participants in the promotion of hemostasis have been described. The intact endothelium produces molecules, such as prostacyclin ($PGI_2$), nitric oxide, and thrombomodulin, which, conjointly with cell-associated ecto-adenophosphatase (ADPase; CD39),[39] inhibit platelet activation. Endothelial injury triggers vasoconstriction, which reduces blood flow and exposes the subendothelial matrix. At this stage, the main platelet glycoprotein (GP) receptors implicated are the members of the GP Ib-IX-V

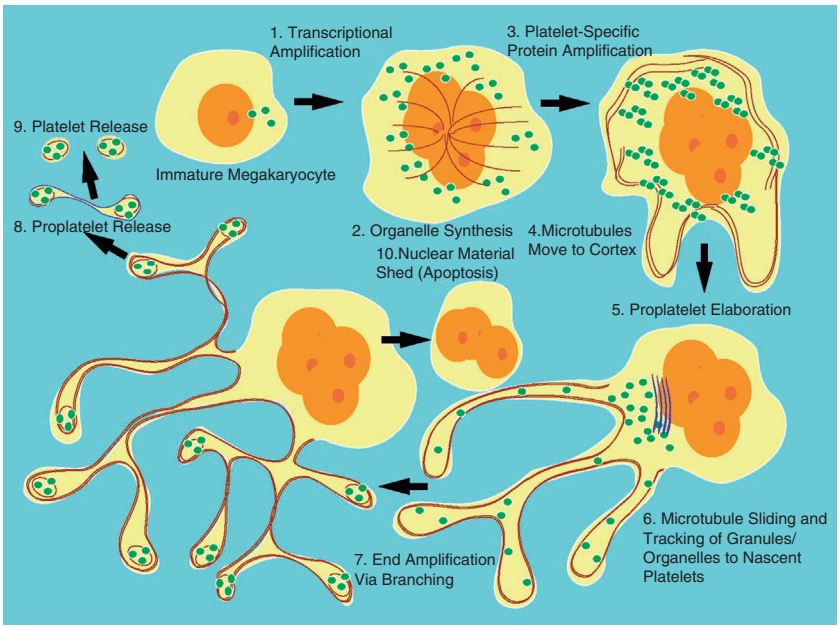

**Figure 16-1** Platelet biogenesis according to the proplatelet model. *(From Italiano JE Jr, Hartwig J: Megakaryocyte development and platelet formation. In Michelson AD, editor:* Platelets*, ed 3, Amsterdam, 2013, Elsevier, pp 27–50.)*

complex (25,000 copies/platelet), and the integrin αIIbβ3 (GPIIb-IIIa complex; 80,000 copies/platelet).[40,41]

Under high shear, the GPIb-IX-V complex attaches to vWF, which is itself bound to the wound rich in collagen fibers, mediating transient adhesion (also referred to as tethering).[42] Glycoprotein VI (GPVI), which is expressed as a complex with the homodimeric Fc receptor γ chain,[43,44] and the integrin α2β1 stabilize the association by binding collagen directly. Although GPIIb-IIIa is a receptor for several ligands (fibronectin, fibrinogen, vWF, thrombospondin, and vitronectin), only its activated form binds fibrinogen. Platelet activation through GPIb-IX and GPVI thus promotes inside-out signaling, leading to GPIIb-IIIa activation and the binding of the latter to fibrinogen, thereby bridging platelets together and recruiting additional platelets onto adhered spread platelets.[40-42,45,46] Deficiency of components of the GPIb-IX-V complex and the GPIIb-IIIa complex leads to the congenital bleeding disorders Bernard-Soulier disease and Glanzmann's thrombasthenia, respectively.[47,48] vWF catabolism is mediated by the metalloprotease ADAMTS-13, which is expressed in plasma and acts as a natural anti-thrombotic agent. Mutations of ADAMTS-13 and depletion by autoantibodies cause familial and acquired thrombocytopenic purpura, respectively.

Platelet activation engages intra-cellular signaling. The actin cytoskeleton pushes the granules toward the platelet membrane. Granule fusion with the plasma membrane is mediated by soluble N-ethylmaleimide-sensitive factor attachment protein (SNAP) receptor (SNARE) complexes, leading to release of granule content through the OCS route.[49] The release of ADP further activates platelets through P2Y12 receptors. Because phospholipids serve as a reservoir of fatty acid, such as arachidonic acid (AA), the cleavage of phospholipids by phospholipase A2 generates lysophospholipids, which can be metabolized into platelet activating factor (PAF) and AA. AA is the substrate of cyclo-oxygenase 1 (COX-1) present in platelets, leading to generation of thromboxane $A_2$.[50] Thromboxane $A_2$ is highly potent at inducing platelet aggregation and vasoconstriction, acting via the thromboxane $A_2$ receptor. As a result, growth of the platelet plug occurs and the blood coagulation cascade is initiated, leading to thrombin generation and fibrin clot formation. In line with the significance of these activation pathways, the inhibition of ADP activity using antagonists of P2Y12 receptors (such as clopidogrel) and of the biosynthesis of thromboxane $A_2$ using COX-1 inhibitors (such as acetylsalicylic acid) is frequently applied in persons at risk of myocardial infarction and thrombotic stroke.

Platelets also respond to activation and shear stress through the release of small extra-cellular vesicles, called microparticles. Microparticles, originally termed "platelet dust" by pioneer investigators,[51] are produced by cytoplasmic blebbing and fission. They measure approximately 100 to 1000 nm in diameter and are distinct from the exosomes that are smaller (50 to 100 nm in diameter) and originate from multivesicular bodies and α-granules through exocytosis.[52] Megakaryocytes can also elaborate microparticles directly, independent of platelet synthesis.[53] Platelets and megakaryocytes are the most abundant source of microparticles in circulating blood, as identified by expression of GPIIb (CD41).[54] During microparticle release, loss of membrane asymmetry generally occurs, leading to exposure of phosphatidylserine (PS) on the microparticle surface.[55] Exposed PS can support blood coagulation.[56] Platelet microparticles are implicated in the pathogenesis of several inflammatory pathologies, including rheumatic diseases (discussed further later).

Beyond their role in the defense of injured blood vessels, platelets appear to play an incompletely understood role in the maintenance of endothelial integrity. Patients with severe thrombocytopenia have been noted to develop

abnormalities of the endothelium such as thinning, fenestrations, and enhanced vascular permeability.[57,58] Accordingly, animals with profound experimental thrombocytopenia experience bleeding at the site of inflammation in skin, lung, or brain.[57-60]

## SIGNALING PATHWAYS IN PLATELET ACTIVATION

ADP, thromboxane $A_2$, and thrombin, the latter through its binding to protease-activating receptors (PARs), share signaling via G protein–coupled receptors (GPCRs).[60,61] However, GPCR signaling is dispensable for the prohemostatic role of platelets in inflammation, pointing to the existence of other significant activation signaling pathways in platelets.

Immunoreceptor tyrosine-based activation motif (ITAM) signaling can play such a role. Platelets express three receptors that belong to the family of ITAM receptors: Fc receptor γIIA (a low affinity receptor for IgG immune complexes),[62] Fc receptor γ chain, which is noncovalently associated with GPVI and is necessary for GPVI function,[43,44] and the C-type lectin 2 (CLEC2), a receptor for podoplanin.[63]

Fc receptor γIIA (FcγRIIA) is expressed on human platelets (but is absent in mice),[62,64] and its activation is critical in the pathogenesis of immune-mediated thrombocytopenia, bacterial sepsis–associated thrombocytopenia, disseminated intravascular coagulation, and various thrombotic manifestations of anti-phospholipid antibody syndrome.[60] Importantly, FcγRIIA also amplifies platelet aggregation and thrombus formation by contributing to integrin outside-in signaling.[60,61]

To determine how platelets prevent hemorrhage during inflammation (previously discussed), transgenic mice expressing a chimeric human IL-4 receptor α/GPIbα (hIL-4Rα/GPIbα) protein instead of GPIbα on the platelet surface were used to induce thrombocytopenia. By infusion of antibodies against hIL-4Rα, profound thrombocytopenia was generated and hemorrhages were detected in the skin after inducing an Arthus reaction. Because wild-type (WT) platelets are insensitive to platelet depletion by anti-IL4Rα (they don't express the chimeric α/GPIbα [hIL-4Rα/GPIbα] protein), WT platelets were transfused in thrombocytopenic mice and could rescue mice from bleeding at the site of inflammation.[59] Importantly, transfused platelets lacking the expression of GPVI and CLEC2 failed to prevent bleeding in skin during an Arthus reaction, demonstrating the key role of GPVI and CLEC2 signaling in the maintenance of endothelial integrity by platelets.[59]

Another prohemostatic role of platelet ITAMs is the separation of blood and lymphatic vessels.[65] Mouse embryos deficient for CLEC2 display blood-filled lymph sacs and die shortly after birth, reminiscent of lethality seen in mice lacking spleen tyrosine kinase (Syk) and SLP-76, two kinases downstream of CLEC2 signaling.[66-69] Blood-filled lymphatic vessels also develop in lethally irradiated mature mice transplanted with bone marrow lacking CLEC2, Syk, or SLP-76 and they die of lymphatic dysfunction, demonstrating that CLEC2 and its signaling are implicated in the separation of blood and lymph in the adult.[60,70] It is not known whether drugs intended to target Syk in the treatment of chronic inflammatory conditions, such as rheumatoid arthritis (RA), might have an impact on blood-lymphatic vessel separation.

Together, these observations illustrate that not all functions of platelets can be blocked simply through "classical" anti-platelet drugs such as antagonists of ADP, acetylsalicylic acid, and thrombin (Figure 16-2).

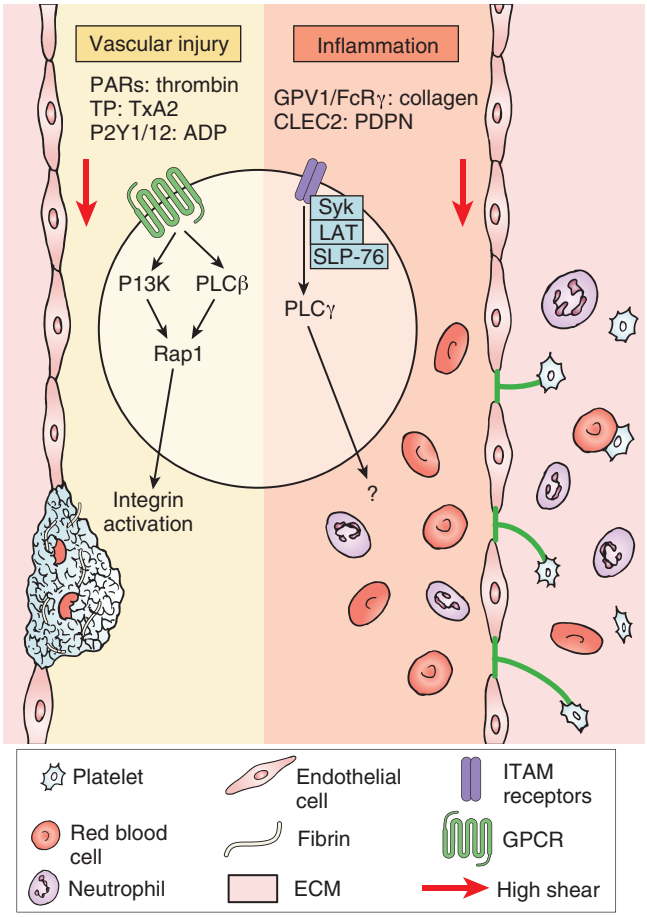

**Figure 16-2** Platelet-dependent hemostasis after vascular injury and at sites of inflammation. Schematic representation of important molecular mechanisms regulating platelet-dependent hemostasis. At sites of vascular injury, platelet activation and adhesion is strongly dependent on soluble agonists and their respective G protein–coupled receptors (GPCRs) expressed on the platelet surface. Engagement of GPCRs leads to the rapid activation of phospholipase Cβ2 (PLCβ2) and phosphatidylinositol 3-kinase (PI3K), events that are critical for the activation of the small guanosine triphosphatase Rap1, affinity regulation in platelet integrins, and platelet aggregate formation. The contribution of immunoreceptor tyrosine-based activation motif (ITAM)–coupled receptors to platelet activation at sites of vascular injury is weak when compared with GPCRs. In contrast, hemostasis at sites of inflammation depends primarily on platelet ITAM signaling and is independent of major platelet adhesion receptors. In these inflammatory conditions, platelets can also contribute to neutrophil extravasation and formation of neutrophil extra-cellular traps. These findings suggest a model in which platelets get activated under low-flow/no-flow conditions in the extravascular space, leading to the release of soluble factors that secure vascular integrity. Both the signaling response downstream of PLCγ2 and the platelet-derived mediator(s) critical for vascular integrity in inflammation are currently unknown. CLEC2, C-type lectin 2; ECM, extra-cellular matrix; FcRγ, Fc receptor γ chain; GPVI, glycoprotein VI; LAT, linker for activation of T cells; PAR, protease activated receptor; PDPN, podoplanin; SLP-76, SH2 containing leukocyte protein of 76 kDa; TP, TxA2 receptor; and TxA2, thromboxane $A_2$. *(Modified from Boulaftali Y, Hess PR, Kahn ML, Bergmeier W: Platelet immunoreceptor tyrosine-based activation motif [ITAM] signaling and vascular integrity.* Circ Res *114:1174–1184, 2014. ## THE PLATELET AS AN INFLAMMATORY CELL

Nucleated thrombocytes, called hemocytes, participate both in hemostasis and in immune defense in lower vertebrates (amphibians, birds, fish, and reptiles).[71] It is generally accepted that these more primitive multifunctional cells slowly evolved to the more specialized role of the mammalian platelets. The platelet nevertheless maintains a broad repertoire of inflammatory mediators, and growing evidence points to an active role of the platelet in innate and adaptive immunity.

Inflammation occurs during innate and adaptive immune responses and in tissue repair and can sometime contribute critically to human disease. A central event in inflammation is the recruitment of leukocytes. When a blood vessel is damaged, not only do platelets rapidly seal the vascular leak, but they also recruit leukocytes that serve to combat potential infection at the injured site. Because of their abundance in blood and their adhesive receptors, platelets are perfectly positioned to have an impact on immune cell extravasation. Platelet P-selectin interacts with leukocyte P-selectin glycoprotein ligand-1 (PSGL-1), allowing leukocytes to roll on adherent activated platelets. Firm adhesion of leukocytes follows through the interaction between leukocyte integrin αMβ2 (CD11b/CD18, Mac-1) and platelet GPIb.[72,73]

CD40L (CD154) is a transmembrane protein part of the tumor necrosis factor (TNF) receptor family that is expressed by both T cells and platelets. Its counterligand CD40 is expressed by macrophages, dendritic cells, B cells, platelets themselves, and other lineages, including endothelial cells. Platelet-derived CD40L can support B cell differentiation and immunoglobulin class switching and induces the expression of intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and release of chemokine (CC motif) ligand 2 (CCL2) by endothelial cells, promoting leukocyte adhesion and extravasation.[71] Because platelets are the largest reservoir of soluble CD40L in human body, plasma levels of CD40L correlate with platelet activation.

Platelets also express Toll-like receptors (TLRs), which are members of a family of pattern recognition receptors that recognize well-conserved molecular motifs common among pathogens. Platelets express TLRs 1 through 9, and platelet TLR stimulation provokes thrombocytopenia and engages TNF production in vivo.[74-77] When platelet TLR4 is activated by bacterial lipopolysaccharide (LPS), it promotes the interaction of platelets with neutrophils, helping to trigger neutrophil degranulation and release of neutrophil extra-cellular traps (NETs) that stretch downstream of the platelet-neutrophil aggregate in blood.[78] NETs are readily observed in RA, systemic lupus erythematosus (SLE), and gout. Whether platelet-induced NETosis is beneficial or detrimental is unclear, but recent observations in gout suggest that NETs may form aggregates that trap cytokines and thereby limit inflammation.[79-82]

Apart from their surface receptors, platelet-derived soluble molecules also contribute to inflammation via mediators including growth factors, cytokines, chemokines, and lipid mediators (Table 16-1). Activated platelets release PDGF and TGF-β, which are responsible for the fibroproliferative response in chronic inflammation. PDGF is chemotactic for smooth muscle cells, fibroblasts, and macrophages and is central in wound healing.[83] Platelets contain a major pool of TGF-β in humans (milligrams of TGF-β/kilogram) and regulate its blood levels.[71] TGF-β is also chemoattractant for leukocytes, and its main function appears to be the inhibition of inflammation, because its systemic administration can reduce the development of inflammatory arthritis in rats,[84] and TGF-β is also necessary for the development of $CD4^+CD25^+FoxP3^+$ regulatory T (Treg) cells.[71] However, fine control of its expression is important because TGF-β overexpression is potentially profibrotic.[85]

Other members of the platelet secretome implicated in the intertwined prohemostatic and pro-inflammatory reactions are the CXC chemokine PF4 and the CC chemokine RANTES, stored in α-granules. Because patients who have gray platelet syndrome (and thus are deficient in platelet α-granules) do not experience recurrent infections, it has been suggested that platelet pro-inflammatory activity may reside in other storage compartments or may reflect newly synthesized mediators. Indeed, activated platelets can rapidly synthesize and release IL-1β.[35,86] In sum, platelets are versatile players in inflammation. The fact that platelets express inflammatory mediators, which appear to be mostly dispensable for their hemostatic functions, supports the idea that they might contribute to inflammatory conditions, such as rheumatic diseases.

## PLATELETS AND RHEUMATIC DISEASES

### Rheumatoid Arthritis

Variations in platelet number and signs of platelet activation are seen in persons with RA. Thrombocytosis (increased platelet number) is frequent in persons with active RA[87,88] and correlates with disease severity and relapses, suggesting that their production might be induced by inflammatory cytokines such as IL-1, IL-6, or TNF.[31,89] By contrast, thrombocytopenia in RA may result from treatments such as gold, cyclophosphamide, methotrexate, and azathioprine that can suppress megakaryocyte development. More rare is drug-induced immune thrombocytopenia, in which immunoglobulin G (IgG)-coated platelets are eliminated in the spleen, a feature seen in 1% to 3% of patients injected intramuscularly with gold salts.[90] In Felty's syndrome, a rare but severe complication in persons with seropositive RA, splenomegaly results in enhanced platelet clearance, but hemorrhage is rare because platelets generally remain above 50,000 platelets per microliter.[91]

In RA, the hallmarks of platelet activation are apparent in both blood and synovial fluid. Platelet-leukocyte aggregates, platelet microparticles, soluble P-selectin, and soluble CD40L are increased in the blood of persons with RA compared with healthy persons. Platelets isolated from the blood of persons with RA are hyperresponsive to stimuli in vitro, suggesting that they might be primed in vivo.[92-100] Platelets and platelet-derived proteins have been identified in the inflamed synovial cavity,[88,101-103] and platelet CLEC2 is detected in synovium in conjunction with platelet thrombi and fibrin deposition in synovial vessels.[104-106] Platelet microparticles, identified through expression of GPIIb (CD41), have been detected in the synovial fluid of

persons with RA.[107-110] Platelet microparticles are much more abundant in RA synovial fluid than in osteoarthritis fluid, but they are also detected at significant levels in joint fluid from active psoriatic arthritis, juvenile idiopathic arthritis, and gout. In RA, platelet microparticles express autoantigens such as citrullinated fibrinogen and vimentin and are coated with autoantibodies and complement in synovial fluid, but not in blood of persons with RA or in psoriatic arthritis synovial fluid.[108,111] Platelet microparticles therefore could represent an important source of autoantigens in persons with RA. Further, platelet microparticles likely represent an important nucleating factor for the immune complexes that are abundant in seropositive, but not seronegative, persons with RA.[112,113]

Whereas adherence of platelets to migrating leukocytes represents one potential route for the accumulation of platelet-derived components in the synovial fluid, a permeable vasculature will also permit direct entry of platelet microparticles. Under inflammatory conditions, platelets can mediate the vascular permeability, leading to extravasation of fluid and tissue edema.[114] Injection of platelet extracts into the skin of human volunteers induces swelling, tenderness, and redness, and platelets injected in the skin of animals triggers neutrophil accumulation and edema.[115]

Because the synovial vasculature is more permeable during RA,[104,105,116,117] the role of platelets in vascular permeability was evaluated in arthritic mice using intravital imaging.[104] Gaps in the blood vessels of the inflamed joint allowed fluorescent microbeads that had been intravenously injected in the tail vein to accumulate inside the synovial tissue, outside the vasculature. Notably, these gaps were absent in healthy mice, and no microbeads could reach nondiseased joints. The gaps were created by platelet-derived serotonin. Serotonin is stored in dense granules after its import through the serotonin transporter, the same serotonin reuptake receptor that is a target of anti-depressant agents, and fluoxetine could reduce the vascular permeability in the arthritic joint.[104] Thus, at least in mice, platelets play a key role in the ongoing maintenance of enhanced vascular permeability in the inflamed synovium.

Platelet depletion in mice reduces joint inflammation in the K/BxN mouse model of arthritis (Figure 16-3).[104,107,118] Using this model, activation of platelets triggered microparticle production through GPVI and occurred independently of P2Y12, GPIb, and thromboxane $A_2$. GPVI-induced microparticles contain both IL-1α and IL-1β and thereby activate fibroblast-like synoviocytes to produce inflammatory cytokines.[107] These results point to GPVI and its ITAM signaling cascade as possible targets for the treatment of arthritis (Figure 16-4).

## Systemic Lupus Erythematosus

Elevated levels of thromboxane,[119] soluble and surface P-selectin,[120-122] platelet-monocyte aggregates,[123] platelet microparticles,[52,97,124] and platelet ultrastructural changes such as blebbing[125] are evident in the blood of patients with SLE. Complement C4d and IgG antibodies against GPIIbIIIa and GPVI[126-128] are reported on the platelet surface in persons with SLE, and it has been suggested that anti-DNA antibodies abundant in SLE may cross-react with GPIIbIIIa.[126]

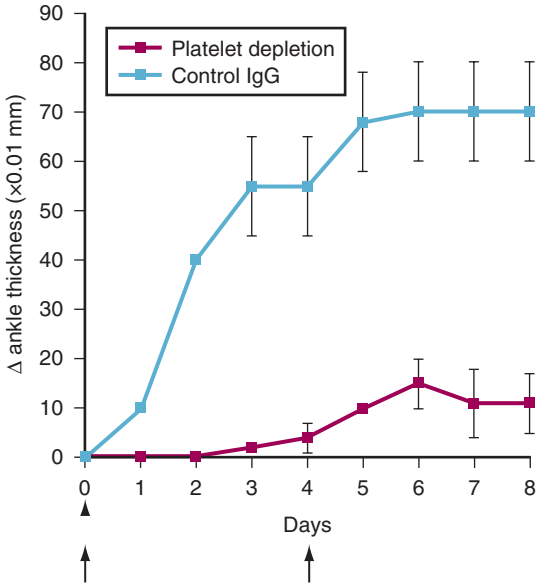

**Figure 16-3** Platelets can be involved in the development of arthritis. The passive K/BxN model of arthritis is induced by administration of arthritogenic serum containing antibodies to glucose-6-phosphate isomerase (GPI). The graph shows arthritis severity after K/BxN serum transfer in mice administered a platelet-depleting antibody *(red squares)* or isotype control *(blue squares)*. Data show the mean ± standard error of the mean (SEM).[42] *Arrows* indicate parenteral administration of platelet-depleting antibody; *arrowhead,* K/BxN serum administration. These findings suggest that platelets are required for arthritis development in vivo in this model. *(From Boilard E, Nigrovic PA, Larabee K, et al: Platelets amplify inflammation in arthritis via co llagen-dependent microparticle production.* Science *327:580–583, 2010.)*

Platelets may also bind immune complexes through FcγRIIA, a receptor implicated genetically in the pathogenesis of SLE.[129,130] Indeed, the sera of persons with SLE, but not of healthy volunteers, trigger expression of the platelet activation marker P-selectin via FcγRIIA.[131,132] Upon activation through FcγRIIA, platelets trigger production of IFN-α by myeloid and plasmacytoid dendritic cells, promoting generation of autoantibodies by B cells.[131] Using SLE-prone mouse models, platelets were shown to actively promote the disease, because platelet depletion and inhibition of platelet function (using P2Y12 blockers) both significantly ameliorate proliferative nephritis[131,133,134] (Figure 16-5).

Patients with SLE are at higher risk of thrombosis, potentially correlating with elevated levels of platelet-derived microparticles.[135] The elevated levels of circulating soluble CD40L in SLE are mainly due to the release of CD40L from activated platelets, correlating with disease activity.[131] The impact of the blockade of CD40L in SLE has been evaluated in two distinct clinical trials. Although inhibition of CD40L in patients with active proliferative lupus nephritis efficiently reduced proteinuria, the trial was terminated prematurely because of thromboembolic events seen in patients treated with the drug.[136] Correspondingly, thrombosis was induced in FcγRIIA transgenic mice intravenously injected with complexes composed of anti-CD40 and soluble CD40L, activating platelets through its unique Fc receptor.[137] In a second study, the inhibition of CD40L failed to have an impact on SLE features, and no adverse events were observed.[136,138]

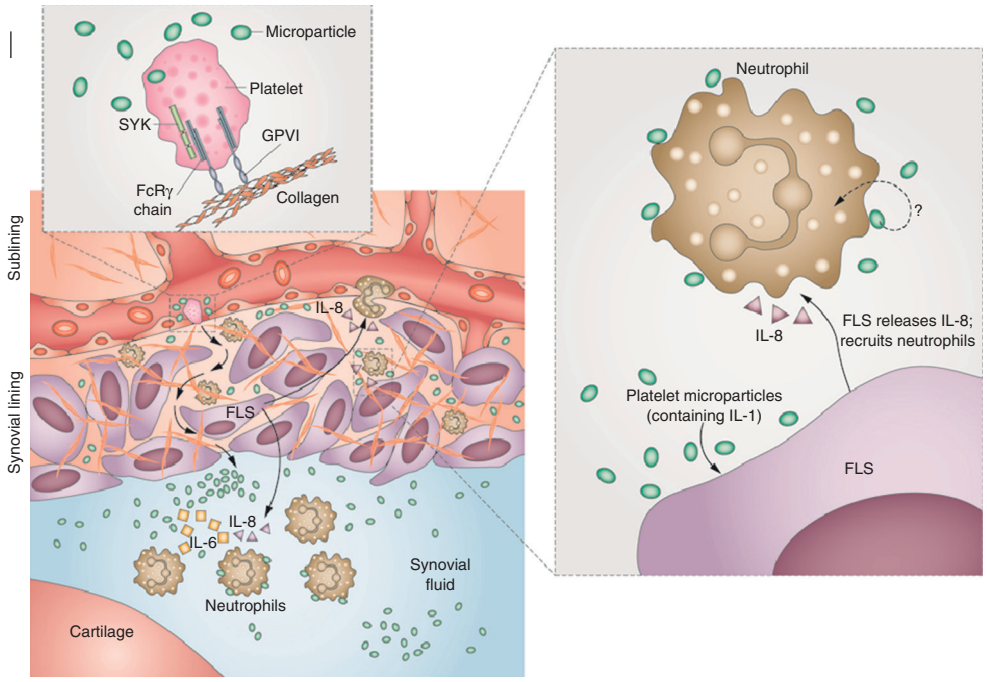

**Figure 16-4** Mechanism by which platelets can enhance inflammation in rheumatoid arthritis. Glycoprotein (GP)VI-expressing platelets activated by GPVI ligands (collagen or laminin) produce interleukin (IL)-1-rich microparticles *(main panel and insets)*. The precise anatomic location of platelet activation and the route by which microparticles enter the joint remain speculative but may implicate transportation by leukocytes and the presence of gaps between the endothelial cells in the joint vasculature and created by platelet-derived serotonin. GPVI stimulation mediates platelet activation via Src kinases and is dependent on SYK activity *(top inset)*. Platelet microparticles (~100 to 1000 nm in diameter), detectable at high levels in inflammatory synovial fluid, interact with tissue cells including fibroblast-like synoviocytes (FLS) and synovial fluid leukocytes *(right inset),* eliciting further inflammatory effector functions from target cells and thereby amplifying synovitis. In the case of FLS, platelet microparticles promote production of IL-6, IL-8 and other mediators capable of leukocyte chemoattraction to the joint *(right inset)*. Platelet microparticles attached to neutrophils, as found in diseased synovial fluid, might also stimulate neutrophil effector functions. *(From Boilard E, Blanco P, Nigrovic PA: Platelets: active players in the pathogenesis of arthritis and SLE.* Nat Rev Rheumatol *8:534–542, 2012. Reprinted with permission from Nature Publishing Group.)*

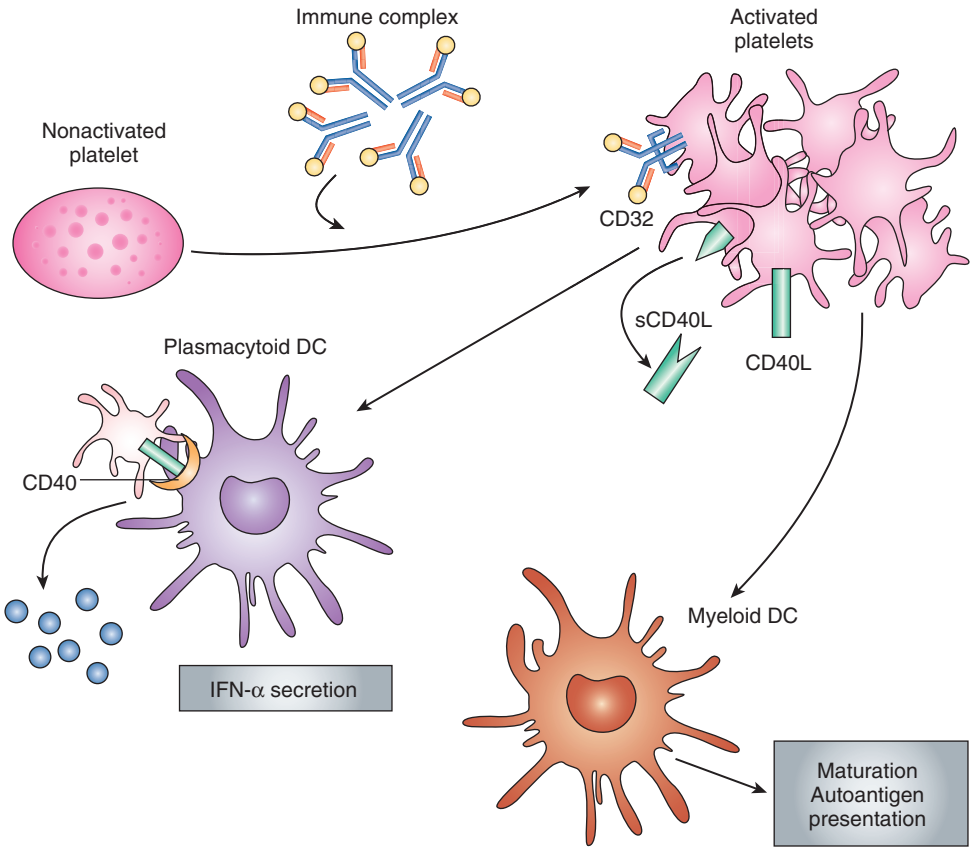

**Figure 16-5** Platelet activation processes involved in systemic lupus erythematosus. Platelest activated by circulating immune complexes express surface CD40 ligand (CD40L), which promote platelet aggregation, binding to myeloid dendritic cells (DCs) to induce their maturation, and binding to plasmacytoid DCs to promote interferon (IFN)-α secretion. sCD40L, Soluble CD40 ligand; SLE, systemic lupus erythematosus. *(From Boilard E, Blanco P, Nigrovic PA: Platelets: active players in the pathogenesis of arthritis and SLE.* Nat Rev Rheumatol *8:534–542, 2012. ## Other Rheumatic Diseases

Platelets most likely participate in other rheumatic disorders. Activated platelets, platelet aggregates, soluble P-selectin, and platelet-derived microparticles have been observed in persons with anti-phospholipid syndrome, systemic sclerosis, ankylosing spondylitis, Arthus reaction, and Raynaud's phenomenon.[123,139-148] Although the treatment of Raynaud's phenomenon by anti-depressants targeting serotonin uptake appears to be effective,[149] pointing to a potential role for platelet-derived serotonin, the actual role of platelets in Raynaud's remains to be established.

# CONCLUSION

A key role of platelets in the prevention of hemorrhage is well known. Platelets also have less generally appreciated roles in the maintenance of endothelial integrity, in the regulation of vascular permeability, in separating blood vessels from lymphatics, and in modulating the severity and course of inflammation. Growing recognition of these non-hemostatic functions has led to a new appreciation of the potential role of platelets in the rheumatic diseases, including RA and lupus. Whereas multiple pathways can contribute to platelet activation, traditional anti-thrombotic agents are unlikely to be sufficient to intervene therapeutically in the immune biology of the platelet. Further research is required to advance our comprehension of the diverse roles of the platelet in host defense and in inflammatory disease, with the ultimate goal of developing ways to interfere selectively with the role of platelets in disease while maintaining their contribution to vascular integrity.

PART 3 EFFECTOR MECHANISMS IN AUTOIMMUNITY AND INFLAMMATION

CHAPTER 17

# Innate Immunity

Steven A. Porcelli

| KEY POINTS |
| --- |
| Innate immunity depends on recognition of conserved molecular patterns found in many microorganisms. |
| Several families of pattern recognition receptors are responsible for triggering innate immune responses. |
| Toll-like receptors and other pattern recognition receptors with leucine-rich repeat domains play a key role in innate immune recognition. |
| Anti-microbial peptides are important effectors of innate immunity. |
| Phagocytic cells and several types of innate-like lymphocytes are key cell types in mediating innate immunity. |
| Innate immune responses have a strong impact on the development of adaptive immunity. |
| Some defects in the innate immune system are associated with a predisposition to infection or to autoimmune disease. |

It has become common practice in immunology to divide the mechanisms involved in host defense into adaptive and innate components. This approach provides a useful framework for classifying the numerous cells, receptors, and effector molecules that combine to make up the vertebrate immune system (Table 17-1). A specific immune response, such as the production of antibodies or T cells against a particular pathogen, is referred to as *adaptive immunity* because it represents an adaptation that occurs during the lifetime of an individual as a result of exposure to that pathogen. Adaptive immune responses involve the clonal expansion of T and B lymphocytes bearing a large repertoire of somatically generated receptors that can be selected to recognize virtually any pathogen. The adaptive immune system of any given person is profoundly molded by the immunologic challenges encountered by that person during the course of a lifetime. A hallmark of adaptive immune responses is that they are highly specific for the triggering agent, and they provide the basis for immunologic memory. This property of memory endows the adaptive immune response with its "anticipatory" property, which provides increased resistance against future infection with the same pathogen and also allows vaccination against future infectious threats.

Adaptive immunity is essential for the survival of all mammals and most other vertebrates, but a wide variety of other mechanisms that do not involve antigen-specific lymphocyte responses are also involved in successful immune protection. These diverse mechanisms are collectively known as *innate immunity* because they are not dependent on prior exposure to specific pathogens for their amplification. Such responses are controlled by the products of germline genes that are inherited and similarly expressed by all healthy persons. Innate immune mechanisms involve both constitutive and inducible components and use a wide variety of recognition and effector mechanisms. It has become clear in recent years that innate immune responses have a profound influence on the generation and outcome of adaptive immune responses. This ability of the innate immune system to instruct the responses of the adaptive immune system suggests many ways in which innate immunity can influence the development of both long-term specific immunity and autoimmune disease.

## EVOLUTIONARY ORIGINS OF INNATE IMMUNITY

In spite of its obvious importance for most vertebrate organisms, the adaptive immune system is a relatively recent evolutionary development (Figure 17-1). In the great majority of present-day vertebrate species, the adaptive immune system is based on the ability to generate large families of variable lymphocyte receptors with immunoglobulin-like structures. This ability has been conserved as a result of the acquisition of a specialized recombination system that mediates the assembly of gene segments in the T cell and B cell receptor families, which most likely occurred through invasion of the genome of a primitive vertebrate by a transposable element or virus carrying this machinery.[1] This critical step in the evolution of the immune system can be traced back to the emergence of the ancestors of present-day jawed fish, which represent the most primitive extant species known to have adaptive immune systems based on the generation of large families of specific immunoglobulin-type receptors.[2] Recently, other systems of variable lymphocyte receptors that are unrelated to immunoglobulins but also provide the basis for an adaptive immune response have been discovered in primitive jawless fish such as lampreys

**TABLE 17-1** Contrasting Features of Innate and Adaptive Immune Systems

| Property | Innate Immune System | Adaptive Immune System |
|---|---|---|
| Receptors | Relatively few (several hundred?)<br>Fixed in genome<br>Gene rearrangement not required | Many (potentially $10^{14}$ or more)<br>Encoded in gene segments<br>Gene rearrangement required |
| Distribution | Nonclonal<br>All cells of a class identical | Clonal<br>All cells of a class distinct |
| Targets | Conserved molecular patterns<br>Lipopolysaccharides<br>Lipoteichoic acids<br>Glycans and peptidoglycans<br>Others | Details of molecular structure<br>Proteins<br>Peptides<br>Carbohydrates |
| Self–non–self-discrimination | Perfect: selected over evolutionary time | Imperfect: selected in individual somatic cells |
| Action time | Immediate or rapid (seconds to hours) | Delayed (days to weeks) |
| Response | Microbicidal effector molecules<br>Anti-microbial peptides<br>Superoxide<br>Nitric oxide<br>Cytokines (IL-1, IL-6, others)<br>Chemokines (IL-8, others) | Clonal expansion or anergy of specific T and B lymphocytes<br>Cytokines (IL-2, IL-4, IFN-γ, others)<br>Specific antibody production<br>Specific cytolytic T cell generation |

IFN, Interferon; IL, interleukin.

Modified from Medzhitov R, Janeway CA Jr: Innate immune recognition. *Annu Rev Immunol* 20:197, 2002.

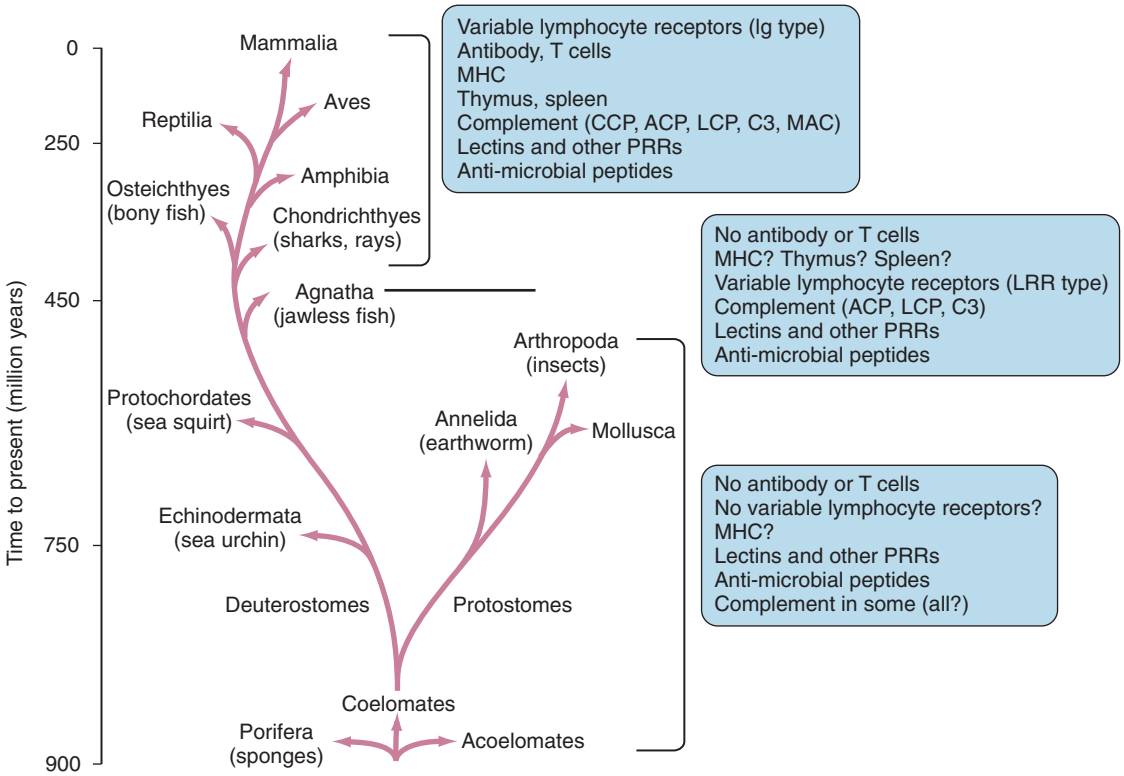

**Figure 17-1** Ancient evolutionary origin of the innate immune system. Studies of the immune systems of a wide range of vertebrates and invertebrates have revealed that even the most primitive invertebrates possess many components of innate immunity (e.g., pattern recognition receptors of the lectin and Toll-like families, anti-microbial peptides, and complement proteins). The innate immune system is thus extremely ancient, having arisen early in the evolution of multicellular life. In contrast, the adaptive immune system is a much more recent development that did not appear until emergence of the ancestors of present-day sharks and rays, approximately 400 million years ago. The first species to acquire an adaptive immune system based on immunoglobulin (Ig)-type receptors must have arisen after the appearance of the direct ancestors of present-day jawless fish (lampreys and hagfish), which are the most highly evolved living species that lack the ability to generate large families of variable Ig-type lymphocyte receptors *(arrow)*. ACP, Alternative complement pathway; CCP, classic complement pathway; LCP, lectin-activated complement pathway; LRR, leucine-rich repeat domain; MAC, membrane attack complex; MHC, major histocompatibility complex; PRR, pattern recognition receptor. *(Modified from Sunyer JO, Zarkadis IK, Lambris JD: Complement diversity: a mechanism for generating immune diversity?* Immunol Today *19:519, 1998.)*

and hagfish.[3] This finding shows that at least two different strategies for the creation of an adaptive immune system emerged at the dawn of vertebrate evolution about 500 million years ago, and it emphasizes the importance of adaptive immunity for survival and further evolution of the vertebrate lineages.

Given this key role of adaptive immunity in the evolution and survival of vertebrates, it is surprising that all invertebrate animals appear to lack the ability to generate lymphocyte populations bearing large families of clonally diverse antigen receptors.[4,5] In these animals, protection against pathogen invasion depends entirely on innate immunity, elements of which appear to exist in all animals and plants and must have evolved with the earliest multicellular forms of life. In many cases, components of the innate immune system are significantly conserved in structure and function in animals from the lowliest invertebrates to the most complex vertebrates. This preservation of innate immune mechanisms, with their functions largely intact, over such vast evolutionary distances is a clear indication of their importance, even in animals that have developed sophisticated adaptive immune responses.

## PATHOGEN RECOGNITION BY THE INNATE IMMUNE SYSTEM

Some mechanisms of innate immunity are constitutive, meaning that they are continuously expressed and are not significantly modulated by the presence or absence of infection. Examples include the barrier functions provided by epithelial surfaces continuously exposed to microbial flora, such as those of the skin and intestinal and genital tracts. In contrast, the inducible mechanisms of innate immunity involve increased production of mediators and upregulation of effector functions that eliminate microorganisms. Induction occurs as a result of exposure to a wide variety of microbes and represents a less specific form of immune recognition than that associated with the specific antibodies and T cells that mediate adaptive immunity. The basic principle underlying this form of response is a process known as *pattern recognition*. This recognition strategy is based on the detection of commonly occurring and conserved molecular patterns that are essential products or structural components of microbes.

## PAMPS AND DAMPS: PATTERNS FOR INNATE IMMUNE RECOGNITION

### Pathogen-Associated Molecular Patterns

The general name given to the targets of innate immune recognition in microbes is *pathogen-associated molecular patterns* (PAMPs). These structural features or components distinctive for microorganisms are not normally found in the animal host. The best-known example of a PAMP is bacterial lipopolysaccharide (LPS), a ubiquitous glycolipid constituent of the outer membranes of gram-negative bacteria. Another important example is the peptidoglycan structure present as the basic cell wall component in nearly all bacteria. These structures may vary partially from one bacterium to another, but the basic elements are conserved, thus providing the possibility of recognizing a broad array of pathogens by sensing a single or a relatively small number of PAMPs. Many PAMPs that serve as targets of recognition for the innate immune response are now known to be associated with bacteria, fungi, and viruses.

In addition to allowing direct recognition of molecules produced by various microorganisms, the innate immune system is able to respond to the patterns of host-derived molecules released by cells undergoing necrotic death. The molecules recognized are generally referred to as *damage-associated molecular patterns* (DAMPs) and include multiple different families of proteins, as well as nonproteinaceous substances such as uric acid microcrystals.[6,7] Thus the response to DAMPs can be an indirect response to microbial invasion, or it can be triggered by other types of tissue damage such as ischemia to result in sterile inflammation.

### Pattern Recognition Receptors

Recognition of PAMPs and DAMPs is mediated by a collection of germline-encoded molecules known collectively as *pattern recognition receptors* (PRRs) (Table 17-2). These receptors are host proteins that have evolved, through many millions of years of natural selection, to possess precisely defined specificities for particular PAMPs or DAMPs expressed by microorganisms. The total number of PRRs present in complex vertebrates such as humans is estimated to be several hundred—a number limited by the size of the genome of any animal and the number of genes it can dedicate to immune protection. The human genome, for example, is estimated to contain approximately 20,000 to 35,000 genes, most of which are not related directly to the immune system. This example demonstrates one of the strong points of contrast between innate and adaptive immune systems, because the latter can possess in the range of $10^{14}$ different somatically generated receptors for foreign antigens in the form of antibodies and T cell receptors. With its much more limited array of receptors, the innate immune system uses the strategy of targeting highly conserved PAMPs that are shared broadly by large classes of microorganisms. Because most pathogens contain PAMPs, this strategy allows the generation of at least partial immunity against most infections.

PRRs are expressed by many cell types; some are specialized effector cells of the immune system (e.g., neutrophils, macrophages, dendritic cells, and lymphocytes), and others are not generally regarded as part of the immune system (e.g., epithelial and endothelial cells). Unlike the T and B cell receptors used for adaptive immune recognition, expression of PRRs is not clonal, which means that all receptors displayed by a given cell type (e.g., macrophages) have identical structure and specificity. When PRRs are engaged by recognition of their associated PAMPs or DAMPs, effector cells bearing the PRRs are triggered to perform their immune effector functions immediately, rather than after undergoing proliferation and expansion, as in the case of adaptive immune responses. This mechanism accounts for the much more rapid onset of innate immune responses.

Considerable progress has been made toward identifying many of the important PRRs involved in the induction of innate immunity. These receptors can be classified into three functional classes: secreted, endocytic, and signaling PRRs (see Table 17-2). In addition, many of the known

**TABLE 17-2** Pattern Recognition Receptors

| Receptor Class | Examples | Prominent Sites of Expression | Major Ligands | Function |
|---|---|---|---|---|
| Secreted PRRs | Collectins<br>Mannan-binding lectin<br>Ficolins<br>Surfactant proteins (SP-A, SP-B)<br>Pentraxins<br>Short pentraxins (CRP, SAP)<br>Long pentraxins | Plasma | Carbohydrate arrays typical of bacterial capsules, fungi, and other microbes<br>Apoptotic cells and cellular debris, including chromatin | Complement activation<br>Opsonization |
| Endocytic PRRs | Lectin-family receptors<br>Macrophage mannose receptor<br>DEC-205<br>Dectin-1<br>Scavenger receptor A<br>MARCO<br>Complement receptors<br>CD11b/CD18 (CR3)<br>CD21/35 (CR2/1) | Macrophages, dendritic cells, some endothelia, epithelia, and smooth muscle cells | Cell wall polysaccharides (mannans and glucans), LPS, LTA, and opsonized cells and particles | Pathogen uptake by phagocytes<br>Delivery of ligands to antigen-processing compartments<br>Clearance of cellular and extra-cellular debris |
| Signaling PRRs | Toll-like receptors<br>CARD/NOD proteins<br>Pyrin domain proteins<br>PYHIN proteins<br>RIG-I-like receptors | Macrophages, dendritic cells, epithelia | Multiple conserved pathogen-associated molecular patterns (LPS, LTA, dsRNA, lipoproteins, flagellin, viral or bacterial DNA, others) | Activation of inducible innate immunity (anti-microbial peptides, cytokines, reactive oxygen or nitrogen intermediates)<br>Instruction of adaptive immune response |

CARD, Caspase activation and recruitment domain; CR, complement receptor; CRP, C-reactive protein; DEC-205, dendritic and epithelial cells, 205 kDa; dsRNA, double-stranded RNA; LPS, lipopolysaccharide; LTA, lipoteichoic acid; MARCO, macrophage receptor with collagenous structure; NOD, nucleotide-binding oligomerization domain; PRR, pattern recognition receptor; PYHIN, pyrin and HIN-200 domain containing proteins; RIG-I, retinoic acid inducible gene-I; SAP, serum amyloid P protein; SP, surfactant protein.

PRRs can be classified into structurally defined families on the basis of a few characteristic protein domains. Among these, the best known include proteins with calcium-dependent lectin domains, scavenger receptor domains, and leucine-rich repeat domains (LRRs).

### Pattern Recognition Receptors of the Lectin Family

Calcium-dependent lectin domains are common modules of secreted and membrane-bound proteins involved in the binding of carbohydrate structures. A well-characterized PRR belonging to this class is the *mannan-binding lectin* (MBL), also known as *soluble mannose-binding protein*, which represents a secreted PRR that functions in initiation of the complement cascade (Figure 17-2).[8,9] This protein is synthesized primarily in the liver on a constitutive basis, although its production can be increased as an acute phase reactant after many types of infection. MBL binds to carbohydrates on the outer membranes and capsules of many bacteria, as well as fungi, some viruses, and parasites. Although mannose and fructose sugars bound by MBL can also be found on the surfaces of normal mammalian cells, they are present at too low a density or in the wrong orientation to efficiently engage the lectin domains of MBL. In contrast, the coats of many microorganisms contain an array of these sugars, which allows strong binding of MBL. Thus, in this case, the spacing and orientation of specific carbohydrate residues constitute the PAMP that triggers the activation of innate immunity by MBL. MBL functions as one of a small number of secreted PRRs that can initiate the lectin pathway of complement activation. At least two other soluble proteins with lectin activity in human plasma, known as *ficolins* (ficolin/P35 and H-ficolin), can also activate this pathway after their interaction with bacterial polysaccharides.[10]

Several of the soluble lectin-type PRRs also play an important role in the opsonization of microbes by binding to their surfaces and directing them to receptors on phagocytic cells. Among these are two pulmonary surfactant proteins, SP-A and SP-D, which similarly recognize and bind to the surface sugar codes of microbes in the respiratory tract.[11] These molecules are similar in structure to MBL, having both collagen-like and lectin domains, and together they constitute a family of soluble PRRs known as *collectins*. Another family of soluble PRRs that performs a similar function in plasma is the pentraxins, so called because they are formed by the association of five identical protein subunits.[12] This family includes the acute-phase reactants C-reactive protein (CRP) and serum amyloid P protein (SAP), along with a number of so-called long pentraxins, which have an extended polypeptide structure with homology to the classic short pentraxins (i.e., CRP and SAP) only at their carboxy-terminal domains. Long pentraxins are expressed in a variety of different tissues and cells, and their specific functions are mostly unknown. However, the long pentraxin PTX3 has been shown to play an important, nonredundant role in resistance to fungal infection in mice, and recent studies indicate that PTX3 is essentially a functional ancestor of antibodies that recognizes microbes and promotes their clearance through complement activation and phagocytosis.[13]

In addition to these soluble proteins, a large number of membrane-bound glycoproteins with lectin domains are known to exist; some of them participate in innate immunity by serving as endocytic PRRs for the uptake of microbes or microbial products[14,15] (Figure 17-3). One of the

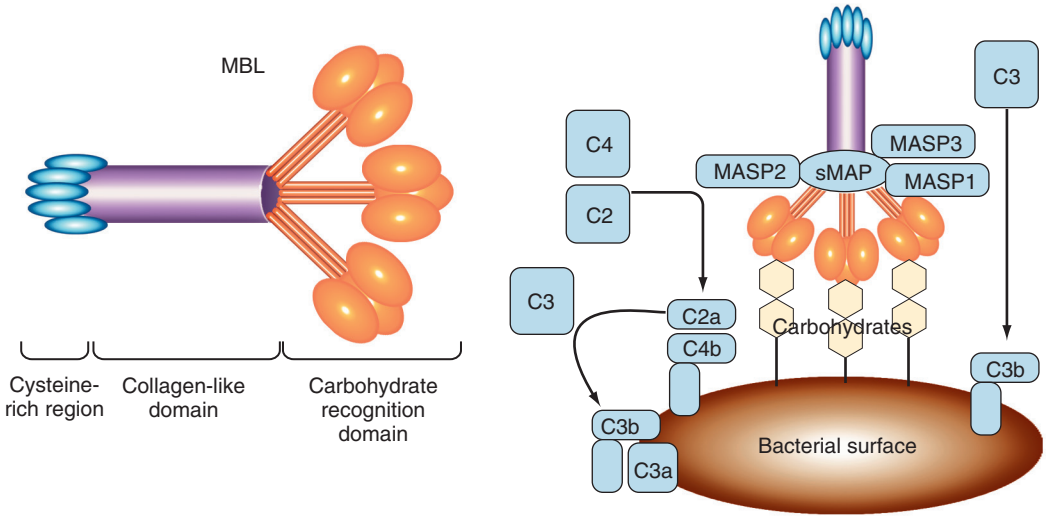

**Figure 17-2** Structure and function of mannan-binding lectin (MBL), a soluble pattern recognition receptor. *Left,* MBL is a multimer protein structure with multiple carbohydrate-binding lectin domains. Three identical 32 kDa polypeptides associate to form a subunit, which then oligomerizes to form functional complexes (the trimeric form consisting of three subunits is illustrated, which is one of several different oligomer sizes that has been observed for MBL). Each polypeptide in the subunit contains an N-terminal cysteine-rich domain, a collagen-like domain, a neck region, and a C-terminal carbohydrate recognition domain. *Right,* Initiation of the lectin pathway for complement activation by MBL. The carbohydrate recognition domains of MBL bind to carbohydrates that are characteristic of bacterial surfaces, which leads to the recruitment of several other serum proteins, including small MBL-associated protein (sMAP) and the three MBL-associated serine proteases (MASP1, MASP2, MASP3). The protease activity of MASP2 cleaves complement C4 and C2 subunits, generating the C3 convertase (C4bC2a). MASP1 is able to cleave C3 directly. The deposition of C3 cleavage products on the bacterial surface results in opsonization and phagocytosis of the bacterial cell.

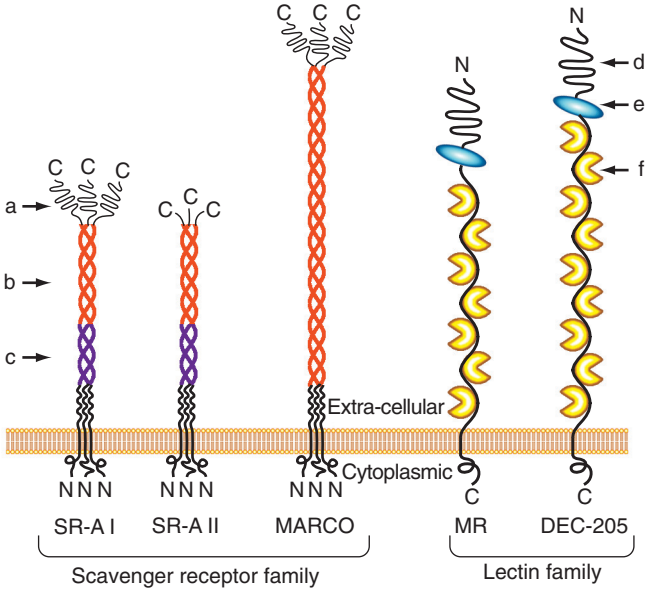

**Figure 17-3** Endocytic pattern recognition receptors of the scavenger receptor and lectin families. *Left,* Illustrations of three members of the scavenger receptor family. These trimeric complexes of type II transmembrane polypeptides have their N-terminals positioned in the cytoplasm and their C-terminals in the extra-cellular space. Three distinct extra-cellular structural domains are indicated: (a) the scavenger receptor cysteine-rich (SRCR) domain (absent in SR-A II), which has no currently known function; (b) the collagen-like domain, which is implicated in the binding of polyanionic ligands; and (c) the α-helical coiled-coil domain (absent in macrophage receptor with collagenous structure [MARCO]), which is believed to assist in receptor trimerization. *Right,* Two examples of multilectin domain endocytic pattern recognition receptors: macrophage mannose receptor (MMR) and DEC-205. Distinct extra-cellular domains in these receptors include (d) a cysteine-rich N-terminal domain, (e) a fibronectin-like domain, and (f) multiple calcium-dependent (C-type) lectin domains that bind various carbohydrate ligands. *(Modified from Peiser L, Mukhopadhyay S, Gordon S: Scavenger receptors in innate immunity.* Curr Opin Immunol *14:123, 2002.)*

most extensively studied of these is the macrophage mannose receptor (MMR).[16] Although originally identified on alveolar macrophages and known to be expressed on macrophage subsets throughout the body, this receptor is also expressed on a variety of other cell types, including certain endothelia, epithelia, and smooth muscle cells. The MMR is a membrane-anchored, multilectin domain–containing protein that mediates the binding of a broad range of pathogens, leading to their internalization via endocytosis and phagocytosis. Although the major function of the MMR appears to be directing the uptake of its ligands, evidence suggests that this receptor may be capable of signaling to modify macrophage functions after receptor engagement.[17] Another member of this receptor family, the β-glucan binding cell-surface lectin known as *dectin-1*, has a role in the modulation of inflammation in a mouse model of infection-induced arthritis.[18]

## Pattern Recognition Receptors of the Scavenger Receptor Family

The scavenger receptor family contains a broad range of structurally diverse cell surface proteins that are expressed most prominently on macrophages, dendritic cells, and endothelial cells[19] (see Figure 17-3). Although they were originally defined by their ability to bind and take up modified serum lipoproteins, they also bind a wide range of other ligands, including bacteria and some of their associated products. Multiple members of this family have been implicated as PRRs for innate immunity, including the scavenger receptor A (SR-A) and a related molecule called the *macrophage receptor with collagenous structure* (MARCO).[20] Both of these molecules contain a scavenger receptor cysteine-rich domain in the distal ends of their membranes and a collagen-like stalk with a triple-helical structure. Both

are known to bind bacteria, and SR-A also binds well-known PAMPs such as lipoteichoic acids and LPS.[21,22] Mice that have been made deficient in SR-A by targeted gene disruption show increased susceptibility to infections caused by a variety of bacteria, thus providing strong evidence of the role of scavenger receptors in protective immunity, most likely through the activation of innate immune mechanisms.[23,24] Members of the class B scavenger receptor family, including CD36 and SR-BI/CLA-1, have also been found to recognize a variety of pathogen-derived molecules.[19] Although these members of the scavenger receptor family clearly function as endocytic PRRs in the uptake of microbes, their potential to serve as signaling receptors has not yet been established. However, several scavenger receptors play a co-receptor role in the signal transduction process mediated by members of the Toll-like receptor (TLR) family (discussed later), most likely by capturing specific ligands and transferring them to adjacent TLRs.[19]

## Pattern Recognition Receptors with Leucine-Rich Repeat Domains

LRRs are structural modules found in many proteins, including PRRs involved in signaling the activation of innate immunity. Molecules in this class include, most notably, the family of mammalian TLRs, which are membrane-bound signal-transducing molecules that play a central role in the recognition of extra-cellular and vacuolar pathogens.[25] Two families of cytoplasmic LRR-containing receptors have also been identified; they play a prominent role in the innate immune recognition of PAMPs expressed by intra-cellular pathogens. These include the families of caspase activation and recruitment domain (CARD) proteins and of pyrin domain proteins.[26] Molecules are closely related in structure and function to proteins found in invertebrates and plants involved in pathogen resistance, highlighting the ancient origin of these pathways for host defense; they appear to have been recognizably conserved throughout approximately 1 billion years of evolution.

**Toll-Like Receptors.** The first member of the Toll family to be discovered was the *Drosophila* Toll protein, which was identified as a component of a signaling pathway that controls dorsoventral polarity during development of the fly embryo.[27] The sequence of Toll showed it to be a transmembrane protein with a large extra-cellular domain containing multiple tandemly repeated LRRs at the N-terminal end, followed by a cysteine-rich domain and an intra-cellular signaling domain (Figure 17-4). A role for Toll in immune responses was suggested by the observation that its intra-cellular domain shows homology to the mammalian interleukin (IL)-1R cytoplasmic domain.[28] This association was later confirmed in studies showing that Toll was critical for the antifungal response in the fly, linking this pathway for the first time to innate immunity.[29] Identification of *Drosophila* Toll eventually led to a search for similar proteins in mammals; this effort has been richly rewarded, yielding

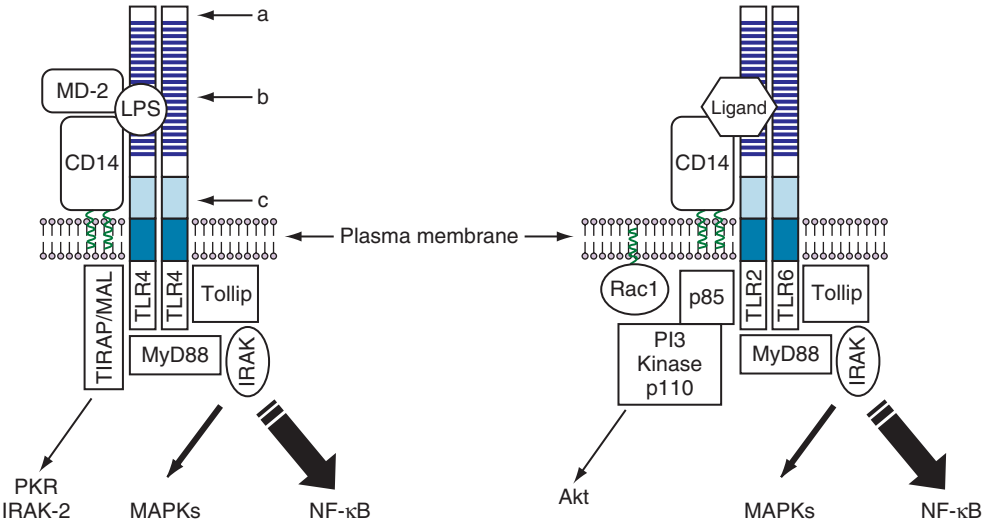

**Figure 17-4** Toll-like receptors (TLRs) and associated proteins. *Left,* TLR4 is a transmembrane polypeptide present in the plasma membrane as a homodimer. The TLR4 polypeptide has three distinct extra-cellular regions: (a) an N-terminal flanking domain; (b) the leucine-rich repeat (LRR) region, which contains 21 leucine-rich motifs and is thought to be directly involved in binding to lipopolysaccharide (LPS) and other ligands; and (c) a C-terminal flanking cysteine-rich domain. The cytoplasmic domains of TLR4 and all other TLRs have homology to the human interleukin (IL)-1 receptor and are designated Toll-IL-1 receptor (TIR) domains. The extra-cellular portion of TLR4 associates with at least two other proteins, CD14 and MD-2, which are involved in ligand recognition. The intra-cellular TIR domains associate with multiple adapter proteins (MyD88, TIRAP/MAL, Tollip), which link the receptor complex to kinases that activate signaling cascades. For TLR4, and probably for most other TLRs as well, activation of the IL-1 receptor–associated kinase (IRAK) is an important step leading to release of the active form of transcription factor nuclear factor-κB (NF-κB). In addition, signaling through TLR4 leads to signal transduction through the activation of mitogen-activated protein kinases (MAPKs), double-stranded RNA-binding protein kinase (PKR), and other members of the IRAK family such as IRAK-2. *Right,* A different set of ligands is recognized by TLR2, which functions as part of a heterodimeric complex with other TLRs such as TLR6. The TLR2-TLR6 complex shares many features with the TLR4 complex in terms of its associated proteins. However, the TIR domain of TLR2 also appears to recruit phosphatidylinositol-3-OH kinase (PI3 kinase, p85, and p110 subunits) and the membrane-associated guanosine triphosphatase Rac1, which allows the activation of other signaling molecules such as the serine-threonine kinase Akt. Thus, although the major signaling pathways activated by different TLRs are similar or identical (i.e., activation of NF-κB and MAPKs), it is likely that each TLR complex has subtle differences in its secondary pathways of signal transduction. These differences may lead to partially overlapping but distinct outcomes in response to ligands recognized by different TLR complexes. *(Modified from Underhill DM, Ozinsky A: Toll-like receptors: key mediators of microbe detection.* Curr Opin Immunol *14:103, 2002.)*

a family of 10 TLRs in humans and 12 in mice.[30] Among these, TLR1 through TLR9 are conserved between mice and humans, TLR10 is present only in humans, and TLR11 through TLR13 are expressed only in mice.[30] All these molecules contain large extra-cellular domains with multiple LRRs, as well as intra-cellular signaling domains known as Toll/IL-1R, or TIR, domains.[31] Many of these TLRs have been linked to innate immune responses against various PAMPs of different microorganisms.[32]

**Toll-Like Receptor 4 and the Response to Lipopolysaccharide.** The first human TLR to be identified was the molecule now designated TLR4, which is a major component in the response to one of the most common of all PAMPs: bacterial LPS.[33] Earlier studies on the response to LPS had identified two proteins—CD14 and LPS-binding protein—as molecules involved in the binding of LPS to the surface of LPS-responsive cells. However, these molecules did not possess any potential for transducing signals into the cell, so it was unclear how LPS binding would lead to the activation of cellular responses associated with gram-negative bacterial infection. The answer was provided by positional cloning studies of the gene responsible for the phenotype in the LPS-hyporesponsive C3H/HeJ mouse.[34] This study revealed a single amino acid substitution in the signaling domain of TLR4. Specific deletion of the *TLR4* gene by targeted gene disruption in mice subsequently confirmed the essential role of this molecule in the response to LPS, because TLR4 knockout mice have almost no response to LPS and are highly resistant to endotoxic shock.[35,36] Biochemical studies provide further support for TLR4 as a component of the LPS receptor; they show that LPS bound to the surface of cells is in close contact with both CD14 and TLR4, as well as another protein called *MD-2*, which appears to perform an accessory function in the binding of LPS to the receptor complex.[37] Additional studies have elucidated many of the downstream elements in the signaling pathways that connect TLR4 to the activation of genes associated with inducible innate immunity[38] (see Figure 17-4). Studies of Toll signaling pathways in *Drosophila* have identified the transcription factor nuclear factor-κB (NF-κB) as one of the key effectors of gene activation after the engagement of Toll. This basic pathway in the fly appears to be largely conserved in TLR signaling in higher animals, including mammals.[39]

**Other Pathogen-Associated Molecular Patterns Recognized by Toll-Like Receptors.** The search for ligands that lead to signaling through various TLRs has demonstrated that this family of PRRs is collectively responsible for innate immune responses to an extraordinary array of PAMPs. In addition to its central role in the signaling of responses to LPS, TLR4 is involved in responses to multiple different self-ligands and non–self-ligands.[32] The antimitotic agent and cancer chemotherapy drug paclitaxel (Taxol) has been shown to mimic LPS-induced signaling in mouse cells through a pathway that requires both TLR4 and MD-2.[40] Other foreign ligands of TLR4 include the fusion protein (F protein) of respiratory syncytial virus[41] and the heat shock protein 60 (HSP60) of chlamydia.[42] TLR4 can signal in response to mammalian HSP60, a protein expressed at increased levels and most likely released by stressed or damaged cells.[43] This represents a variation of the pattern recognition principle in which the pattern is an endogenous molecule released by damaged host cells that serves as a DAMP, rather than a PAMP produced directly by a pathogen. Other examples of recognition of DAMPs by TLR4 include responses to oligosaccharide breakdown products of tissue hyaluronans and responses to the extra-domain A region of fibronectin produced by alternative RNA splicing in response to tissue injury or inflammation.[32,44]

The range of PAMPs recognized through TLR2 is probably even greater than for TLR4. TLR2 is known to be involved in signaling in response to multiple PAMPs of gram-negative and gram-positive bacteria, including such structures as bacterial glycolipids, bacterial lipoproteins, parasite-derived glycolipids, and fungal cell wall polysaccharides.[32] TLR2 does not function independently in responding to these PAMPs; rather, it forms heterodimers with TLR1 or TLR6. This ability to pair with other TLRs appears to be unique to TLR2, because other TLRs that have been studied carefully (e.g., TLR4 and TLR5) most likely function only as monomers or homodimers. Other TLRs with currently defined ligands are TLR5 (involved in the response to bacterial flagellin), TLR3 (double-stranded RNA), TLR7 (single-stranded RNA), and TLR9 (unmethylated bacterial DNA).[32] It is apparent that most, if not all, microbes contain multiple PAMPs that are recognized by different TLRs. For example, a typical bacterium expressing LPS also contains unmethylated DNA and thus generates signals not only through TLR4 but potentially through TLR9 as well. Because different TLRs are capable of activating distinct signaling cascades (see Figure 17-4), the ability of a single cell to detect several different features of a pathogen simultaneously with multiple TLRs may help the innate immune response to be more finely tuned to respond to a particular challenge.[45]

**CARD and Pyrin Domain Proteins.** A large number of cytosolic proteins that have structural similarities to membrane-bound TLRs and that function as sensors for PAMPs of intra-cellular pathogens and as regulators of innate immune responses have been identified. Many of these proteins contain LRR domains and have been classified on the basis of their incorporation of a CARD or pyrin domain. The nomenclature and classification schemes for this growing family of innate immune sensors and regulators are still evolving, and it has been proposed that they should be grouped and classified as members of a single family designated the CATERPILLER (CARD, R [purine]-binding, pyrin, lots of leucine repeats) family.[46] However, the most recent literature shows a trend toward referring to this group of proteins as the *NLR family*, an acronym that stands for either "nucleotide-binding domain, leucine-rich repeat proteins"[47] or "Nod-like receptors."[30] The first intra-cellular microbial sensors in this family to be described were the Nod1 and Nod2 proteins, which contain LRR domains linked to a central nucleotide binding and oligomerization (NOD or NACHT) domain and an N-terminal CARD domain.[48] As in the case of TLRs, the LRR domains of these proteins appear to be involved in the recognition of pathogen-derived molecules and a variety of host components that function as DAMPs, and their CARD domains are linked to downstream signaling for the activation of innate immunity. Although originally implicated in the response to bacterial LPS, it is now well accepted that both

Nod1 and Nod2 are primarily involved in the recognition of muropeptide monomers released from bacterial cell wall peptidoglycans.[26] Signals resulting from the recognition of peptidoglycan components by Nod1 and Nod2 lead to activation of the NF-κB pathway, as in the case of TLR signaling. However, other signaling pathways also appear to be engaged, such as activation of procaspase-1 and caspase-9 by CARD domain interactions, leading to increased production of IL-1β and cell death through a process referred to as *pyroptosis*.[47]

The pyrin domain–containing proteins represent a major subgroup of NLRs that are believed to signal in response to microbial invasion or cellular stress. The prototype member of this family is pyrin, which is the product of the gene that is mutated in persons with familial Mediterranean fever.[46] Although pyrin itself lacks an LRR domain, numerous other members of this family contain an LRR linked to a central NOD domain and an N-terminal pyrin domain. These family members include cryopyrin (also known as NLRP3 or NALP3), which is mutated in patients with a range of hereditary inflammatory diseases referred to collectively as *cryopyrin-associated periodic syndromes*.[47] Cryopyrin, together with these multiple related proteins, constitutes a large set of related proteins known as the NLRP (NLR-PYRIN domain) or NALP (NACHT-LRR-PYRIN domain–containing proteins) family.[26] The human genome contains 14 genes encoding NLRP proteins, the precise functions of which are still largely unknown.[30] However, several NLRP proteins, particularly NLRP3 and NLRP1, have been identified as key components in the formation of intra-cellular complexes known as *inflammasomes*. These cytosolic protein complexes serve as activating platforms that are involved in the activation of caspases—that is, intra-cellular proteases required for the processing of inflammatory cytokines such as IL-1β and IL-18.[47,49] Direct recognition of specific PAMPs by NLRP proteins remains to be established, although initial studies implicate these proteins as direct or indirect sensors of various stimuli, including constituents of bacteria (peptidoglycan, bacterial RNA, and exotoxins), viruses (double-stranded RNA), and uric acid crystals.[30,47,50–53]

In addition to the likely role of NLRP proteins in sensing foreign nucleic acids as PAMPs, recent studies have characterized a complex array of other proteins that serve as sensors for intra-cellular DNA or RNA and are likely to play major roles in anti-viral innate immunity. One prominent example is the family of PYHIN proteins, which are cytosolic or nuclear proteins containing PYRIN domains linked to a DNA-binding domain known as HIN-200.[54] Some of these proteins, such as the absent in melanoma-2 (AIM2) protein, have been clearly established to act as sensors for intra-cellular viral DNA that can trigger a range of innate immune responses. A range of other candidate intra-cellular proteins have been identified that may make important contributions to the innate response to DNA, particularly those that act through signaling pathways mediated by the adaptor protein called stimulator of interferon genes (STING).[55] Among the growing list of cytosolic RNA sensing proteins, the most well studied at present are the RIG-I-like receptors (RLRs). The RLRs include the retinoic acid–inducible gene-I (RIG-I), melanoma differentiation factor 5 (MDA5), and laboratory of genetics and physiology 2 (LGP2) proteins.[56] These proteins are expressed in the cytosol of most cells and respond to structural motifs present in many viral RNA molecules to induce type I interferon (IFN) and other anti-viral effectors.

## EFFECTOR MECHANISMS OF INNATE IMMUNE RESPONSES

The ability to recognize pathogens through PRRs allows activation of numerous anti-microbial effector mechanisms by the innate immune response. These responses lead to the killing of pathogens through production of effector molecules with direct microbicidal activities, including the membrane attack complex of complement, a variety of anti-microbial peptides, and the caustic reactive oxygen and reactive nitrogen intermediates generated within phagocytic cells. In invertebrates, these mechanisms represent virtually the entire protective response against microbial invaders. However, in most vertebrates, including mammals, innate immune recognition also has profound effects on triggering and programming the adaptive immune response that follows somewhat later. This ability of the innate immune system to instruct the adaptive response has major implications for the development of long-term protective immunity to infection and may play a critical role in mechanisms leading to autoimmunity.

## CELL TYPES MEDIATING INNATE IMMUNITY

Many types of cells have the ability to mount at least a limited response to PAMPs, but the most effective cell types in this regard are the specialized phagocytes, such as macrophages, neutrophils, and dendritic cells. Upon recognition of microbial stimuli, these cells have the ability to upregulate nicotinamide adenine dinucleotide phosphate (NADPH) oxidase by assembling the components of this enzyme complex on phagosomal membranes, leading to an oxidative burst that produces microbicidal superoxide ions.[57] Many phagocytic cells also increase their expression of inducible nitric oxide synthase (iNOS, or NOS2) upon contact with various PAMPs.[58] This increased expression leads to the production of reactive nitrogen intermediates, including nitric oxide and peroxynitrite, which have potent direct antimicrobicidal activities. These responses are synergistic because the anti-microbial activity of the phagocyte oxidase system is frequently enhanced by the expression of reactive nitrogen intermediates.

### Innate-like Lymphocytes

A number of distinct lymphocyte subsets also play important roles in innate immune responses. Among these subsets are a complex mixture of lymphocytes that lack markers of the T and B cell lineages and are collectively referred to as innate lymphoid cells (ILCs). The complexity of ILC populations is currently still being unraveled. Recent classifications recognize three distinct lineages designated ILC1, ILC2, and ILC3 cells that are distinguished by phenotypic markers and by secretion of different cytokines.[59] The ILC1 subset is composed of IFN-γ–secreting populations, which include natural killer (NK) cells. These lymphocytes do not express receptors generated by somatic recombination and thus depend on germline-encoded receptors for signaling

their responses against pathogen-infected cells.[59] NK cells participate in the early innate response against virally, and probably bacterially, infected cells through expression of cytotoxic activity and secretion of cytokines.[60]

Several other subsets of lymphocytes belonging to the T and B cell lineages have been identified as participants in the rapid response against pathogens to which the host has not previously been exposed. Although these cells express clonally variable, somatically rearranged antigen receptors (T cell antigen receptors or membrane immunoglobulins) and thus could be classified as components of the adaptive immune system, their manner of functioning is much more characteristic of innate than adaptive immunity. These innate-like lymphocytes (ILLs) may represent remnants of the earliest primitive adaptive immune system, and they appear to have been conserved to varying degrees because they continue to make specialized contributions to host immunity.[61]

Among the currently recognized ILLs are two B cell populations, known as the B1 and marginal zone B cell subsets.[62,63] These B cell populations are involved in the spontaneous production of natural antibodies, which are largely germline-encoded immunoglobulins that are reactive to commonly expressed microbial determinants. In addition, both of these B cell populations generate rapid T cell–independent responses after bacterial challenges and thus contribute to the first line of immune defense that precedes the onset of adaptive immunity.

Among the T cells, three populations of ILLs have been identified and characterized in detail: γδ T cells, NK T cells, and mucosal-associated invariant T (MAIT) cells. The γδ T cells express somatically rearranging receptors that use a limited number of variable region genes and are thought to recognize a narrow spectrum of foreign or self-ligands.[64] In humans, the specificities of two subsets of γδ T cells have been at least partially defined. One of these subsets, the major circulating population expressing the Vδ2 gene product, responds rapidly and without prior immunization to a variety of small alkyl phosphate and alkyl amine compounds that are produced by many bacteria. Another subset, characterized by its expression of the Vδ1 gene product, responds to class I major histocompatibility complex (MHC)–related self-molecules of the class I MHC chain–related A and B (MICA/B) and CD1 families.[64] These molecules may serve as markers of cellular stress and are upregulated on cells in the context of infection or inflammation, leading to the activation of Vδ1-bearing γδ T cells.

A similar principle appears to be involved in the functioning of NK T cells, which are so named because of their co-expression of an αβ T cell antigen receptor and a variety of receptor molecules that are typically associated with NK cells.[65] Similar to γδ T cells, NK T cells have somatically rearranged antigen receptors that use a limited array of V genes and most likely recognize a narrow range of foreign or self-antigens. A major population of NK T cells is reactive with the class I MHC–like CD1d molecule, and these ILLs appear to be activated by recognition of a variety of lipid or glycolipid ligands that can be presented by CD1d. Recently, several bacterial glycolipids have been identified as specific antigens that stimulate NK T cells, suggesting that these cells may be rapid responders that contribute to innate antibacterial immunity.[65] A wide variety of mouse disease models have shown that NK T cells also make significant contributions to the development of adaptive immune responses and may play a particularly important role in immunoregulation to prevent autoimmunity.[65] Similarly, MAIT cells are a separate population of innate-like T cells that have recently been shown to use their αβ T cell antigen receptors to recognize common vitamin B metabolites that are produced and secreted by a wide range of bacteria.[66]

### Anti-microbial Peptides

Anti-microbial peptides are the key effector molecules of inducible innate immunity in many invertebrates and are being increasingly recognized as important elements of innate immunity in higher animal species, including mammals.[67] They are evolutionarily ancient components of host defense that are widely distributed throughout all multicellular organisms in the animal and plant kingdoms. More than 1000 such peptides have been identified, and their diversity is so great that it is difficult to categorize them. However, at a structural and mechanistic level, most of these peptides share several basic features. They generally are composed of amino acids arranged to create an amphipathic structure with hydrophobic and cationic regions. The cationic regions target a fundamental difference in membrane design between microbes and multicellular animals, which is the abundance of negatively charged phospholipid head groups on the outer leaflet of the lipid bilayer. The preferential association of anti-microbial peptides with microbial membranes leads to membrane-disrupting activity, most likely involving the interaction of the hydrophobic regions of the peptide with membrane lipids.[68]

Anti-microbial peptides produced in response to engagement of various PRRs account for most of the inducible immunity against microbes noted in many invertebrate animals and plants. Although these peptides are probably less central to host immunity in most vertebrates, evidence indicates that they make important contributions to immunity in more highly evolved animals, including mammals.[69] In humans, active anti-microbial peptides, such as the α- and β-defensins, are constitutively or inducibly produced in skin and epithelia of the gastrointestinal and respiratory tracts.[70] These molecules most likely act as natural preservatives of epithelia that are colonized or frequently exposed to microbial flora. Because the acquisition of resistance against these agents by sensitive microbial strains is extremely unusual, anti-microbial peptides are of great interest as templates for the development of new anti-microbial pharmaceuticals.[70,71]

## INFLUENCE OF INNATE MECHANISMS ON ADAPTIVE IMMUNITY

In addition to functioning as a first line of defense against invading pathogens, a critical feature of the innate immune system in higher animals such as mammals is its effect on activating the adaptive immune system. In fact, it is now clear that in most situations, the adaptive immune system mounts a response to a pathogen only after the pathogen has generated signals via PRRs of the innate immune system. This principle serves as the basis for the adjuvant

effect, which is the observation that antibody and T cell responses are efficiently generated against protein antigens only if these are introduced together with a nonspecific activator of the immune system, which is generically known as an *adjuvant*. Most adjuvants are in fact extracts or products of bacteria, and it is clear that in most or all cases, adjuvant effects result from activation of the innate immune response.[72]

Innate immune responses can prime or potentiate the adaptive immune response in many ways (Figure 17-5). In the case of T cell responses, one extremely important and well-recognized mechanism involves the upregulation of co-stimulatory molecules. T cells require at least two signals to become activated from a naïve resting state. One signal is provided through the T cell antigen receptor by its binding to a specific peptide ligand presented by an class I or II MHC molecule. The second signal is provided by one of several co-stimulatory ligands that are expressed by specialized antigen-presenting cells such as dendritic cells. The best studied of these are the molecules of the B7 family—B7-1 (CD80) and B7-2 (CD86)—which engage the activating receptor CD28 on the surface of the T cell. Expression of B7 family co-stimulatory molecules on the surface of antigen-presenting cells is controlled by the innate immune system, such that these molecules are induced to appear at functional levels only after PRRs, such as members of the TLR family, have been activated by recognition of their cognate PAMPs or DAMPs.[33]

Recent studies have shown that innate immune signaling through TLRs has a major impact on the responses of phagocytic antigen-presenting cells; it also provides an important second signal for immunoglobulin production by B cells. In the case of phagocytic cells, uptake of microbes by phagocytosis and subsequent maturation of the phagosome are stimulated by concurrent TLR signaling.[73] In dendritic cells, which are the predominant antigen-presenting cells for the priming of T cell responses, TLR signaling has a major impact on whether antigens from phagocytosed microbes are effectively presented on class II MHC molecules.[74] For B cells responding to foreign antigens, it has been demonstrated that concurrent signaling through TLRs is necessary for the efficient stimulation of T cell–dependent differentiation into plasma cells and subsequent antibody secretion.[75] This concept is also relevant for T cell responses

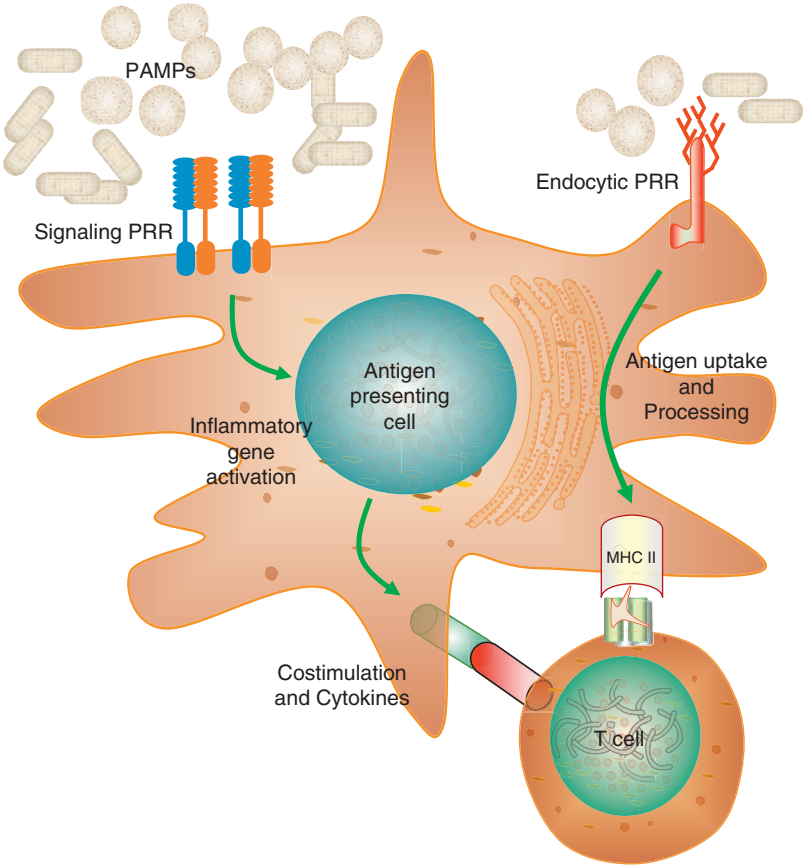

**Figure 17-5** Instruction on the adaptive immune response by the innate immune system. When an antigen-presenting cell (APC) comes into contact with pathogen-bearing pathogen-associated molecular patterns (PAMPs), responses are triggered via innate immune mechanisms that dramatically alter the ability of the APC to stimulate an adaptive (T cell–mediated) immune response. For example, signals generated by contact with PAMPs such as lipopolysaccharide (LPS) with Toll-like receptor 4 (TLR4) lead to the activation of transcription factor nuclear factor-κB (NF-κB), which enters the nucleus of the APC and assists in switching on genes for cytokines (e.g., interleukin [IL]-1, -6, and -12 and a variety of chemokines) and co-stimulatory molecules (e.g., the B7 family members CD80 and CD86). In addition, binding of the pathogen to endocytic pattern recognition receptors (PRRs) such as the mannose receptor (MR) leads to delivery of the pathogen to endosomes (Endo) and lysosomes (Lys). There, the protein antigens of the pathogen are partially degraded to generate antigenic peptides that can be presented by class II major histocompatibility complex (MHC) molecules for recognition by the T cell antigen receptors (TCRs) of specific T cells. These effects of pattern recognition by the innate immune system lead to expression of the signals required for activation of quiescent antigen-specific T cells and the subsequent generation of specific antibodies.

to autoantigens, including several prominent nuclear antigens that are targets of autoantibodies in rheumatic disease.[76,77]

Innate immune responses also trigger the production of many cytokines and chemokines, which enhance the development of adaptive immune responses and change the nature of the adaptive response generated. For example, contact between dendritic cells and PAMPs such as LPS or bacterial lipoproteins leads to the production of IL-12 as a result of signaling through TLRs.[72,78] This cytokine acts on antigen-specific T cells to promote their differentiation into T helper type 1 cells, which are associated with the production of IFN-γ and other effector mechanisms that favor the clearance of bacterial pathogens.[79] In the case of myeloid lineage dendritic cells, signaling through TLRs (and potentially other PRRs) induces a process known as *maturation*, which is associated with increased expression of antigen-presenting and co-stimulatory molecules that enables the efficient priming of naïve antigen-specific T cells.[80]

This requirement for the innate immune response to "switch on" the expression of molecules required for the priming and differentiation of T cell responses helps ensure that pro-inflammatory adaptive immune responses occur mainly in the setting of a relevant infectious challenge. After activation, helper T cells control other components of adaptive immunity, such as the activation of cytotoxic T cells, B cells, and macrophages. Innate immune recognition, therefore, appears to control all major aspects of the adaptive immune response through the initial recognition of infectious microbes by PRRs. The discovery of self-molecules that act as DAMPs further extends this paradigm to include immune responses that are triggered by tissue damage. This more extended view, sometimes referred to as the "danger model," helps explain why certain self-ligands produced or released in the setting of infection or tissue damage can function in essentially the same manner as the PAMPs associated with microorganisms.[81,82]

## DISEASE ASSOCIATIONS INVOLVING INNATE IMMUNITY

Given the obvious role of the innate immune response in virtually all types of infectious disease, one might expect that gross defects in the mechanisms of innate immunity occur relatively rarely and in association with clinical immunodeficiency. In fact, increasing evidence indicates that mutations that inactivate various innate immune pathways can lead to increased pathogen sensitivity in both laboratory mice and humans.[8,23,69,83,84] Because many of the pathways leading to innate immunity are amplified during recurrent or prolonged activation of the immune system, they must also participate in mediating tissue damage in chronic inflammatory disease. In addition, certain self-molecules that are produced or released at increased levels as a result of inflammation, including heat shock proteins, nucleic acids, and microcrystals of monosodium urate or calcium pyrophosphate, may act as DAMPs.[42,76,77,85,86] These self-molecules may signal through TLRs or other PRRs to stimulate adjuvant-like effects that increase the potential for autoreactive lymphocytes to be activated.

Perhaps a more surprising finding has been that some defects in innate immunity are associated with a markedly increased predisposition to autoimmune disease. Several different mechanisms have been proposed to explain this paradoxical association. Mechanisms of the innate immune response play an important role in the clearance of self-antigens released from necrotic or apoptotic cells, resulting in a non-inflammatory clearance of self-antigens that tends to favor tolerance rather than the stimulation of immune responses.[87] Failure of such clearance may lead to excessive exposure to self-antigens, triggering normally silent autoreactive lymphocyte clones to expand and differentiate into effector cells. This mechanism may account for the development of lupus-like autoimmunity in mice with targeted deletion of the gene for the short pentraxin SAP, which, along with other components of the innate immune system, appears to play a significant role in the clearance of DNA-chromatin complexes.[88] Reduced levels of serum mannose-binding lectin in humans also appear to be a risk factor for the development of systemic lupus erythematosus, possibly because of the role of this soluble PRR in facilitating the clearance of apoptotic cells.[89]

Deficiencies of early components of the classic pathway of complement activation have been strongly associated with lupus-like autoimmunity in both humans and mouse models.[90-94] This association may be the result of alterations in the clearance of apoptotic cells or other sources of self-antigens, resulting in increased stimulation of normally silent autoreactive lymphocytes.[95,96] An alternative, but nonexclusive, mechanism relates to involvement of the complement system, particularly the early components C1 and C4, in facilitating the induction of self-tolerance by the adaptive immune system by increasing the localization of autoantigens such as double-stranded DNA and nucleoproteins within the primary lymphoid compartment.[90,97,98] Thus, a deficiency of C1 or C4 appears to result in the failure to delete or functionally inactivate autoreactive B cell clones as they arise during lymphopoiesis in the bone marrow.[97,99] Studies carried out in mouse models suggest that this tolerance-inducing mechanism is partially disrupted in animals that are deficient in a variety of other components of innate immunity, including SAP and the complement receptors CD21/CD35.[88,97]

Multiple examples of links between defects in signaling receptors of the innate immune system and chronic inflammatory diseases have emerged from studies of the CARD and pyrin families of cytosolic PRRs.[30,47] The first association of this type was provided by genetic mapping studies that identified the Nod2 protein as the product of the inflammatory bowel disease 1 (IBD1) locus, which contributes to disease susceptibility in a subset of patients with Crohn's disease.[100-103] This soluble PRR of the CARD family normally functions by inducing cytokine production in response to bacterial peptidoglycan, but mutant alleles associated with increased risk of Crohn's disease are defective in this function.[100] In this case, it may be failure of innate immunity to adequately control bacterial colonization or infection in the intestine that leads to the final expression of disease. Consistent with this view, a recent study has demonstrated diminished expression of a class of anti-microbial peptides (β-defensins known as *cryptdins*) in Paneth cells from the ileum of patients with Crohn's disease and *Nod2* mutations.[104] Other findings suggest that defective signaling by mutant variants of *Nod2* can result in reduced production

of immunoregulatory cytokines such as IL-10, perhaps resulting in uncontrolled inflammation in the intestine.[105] Other studies have established links between various members of the pyrin family and specific chronic inflammatory disorders. These links include the causative association of mutations in pyrin with familial Mediterranean fever and of cryopyrin with cryopyrin-associated periodic syndromes.[46,47] These diseases and other chronic inflammatory or autoimmune disorders associated with specific deficiencies in innate immune mechanisms are frequently considered together as autoinflammatory diseases.[106] Recognition that these diseases are frequently associated with dysregulation of inflammatory cytokine production, in particular IL-1β, has led to some striking therapeutic advances in the treatment of selected patients using systemic administration of the IL-1 receptor antagonist anakinra.[107-109]

Deficiencies in at least two populations of ILLs—NK cells and NK T cells—have been associated with multiple autoimmune syndromes in both humans and mice.[65,110-112] This finding is believed to reflect a significant role for these ILLs in regulating adaptive immune responses, although the precise mechanisms by which they act still are not fully understood. Given the complex interplay between innate immunity and adaptive immunity, it is extremely likely that associations between alterations in innate immunity and autoimmune diseases will continue to emerge. As for some of the examples cited here, a fuller understanding of these associations is likely to lead to new and successful therapies for autoimmune and autoinflammatory diseases.

## FUTURE DIRECTIONS

In the past two decades of research in immunology, we have seen a great emphasis on the fundamental role played by innate immune mechanisms in all immune responses. The innate immune system in humans represents the accumulation of many stages of evolution and natural selection that began with the most primitive organisms. Because of the ancient origins of the innate immune system, some of the most important discoveries in the field of innate immunity have come from studies of relatively simple animals such as flies and worms. Now that many of the pieces of this elaborate system have been discovered and categorized, continued research efforts are turning increasingly toward exploring the roles of various components of innate immunity in the human immune system. These efforts are very likely to yield insights into many currently unexplained diseases and may provide targets for new therapeutics.

## CONNECTION TO THE CLINIC

- Innate immune responses serve as the foundation of all immunity; they participate at some level in all infectious, inflammatory, and autoimmune diseases.
- Drugs targeting specific innate immune effectors are beginning to emerge as useful therapeutic agents.
- Innate immune receptors are responsible for triggering the clinical syndromes associated with uric acid crystals and potentially other types of crystal-induced arthritis.
- Primary defects in specific innate immune molecules have been identified as the cause of a range of uncommon disorders known as *autoinflammatory diseases*.
- Many systemic autoimmune diseases are associated with genetic polymorphisms of molecules involved in innate immune responses.
- Research into innate immunity has provided important new insight into potential mechanisms for common autoimmune diseases such as Crohn's disease and systemic lupus erythematosus.

CHAPTER 18

# Adaptive Immunity and Organization of Lymphoid Tissues

Michael L. Dustin

**KEY POINTS**

- Lymphocytes are born, and many self-reactive cells are deleted, in primary lymphoid tissues.
- Immune responses are usually initiated in secondary lymphoid tissues.
- Tertiary lymphoid tissue can be generated at sites of inflammation and may promote tissue-specific autoimmunity.
- Self-tolerance is established by antigen recognition in primary lymphoid tissues or elsewhere in the absence of inflammation.
- Generation of an adaptive immune response is dependent on innate immune system activation.
- Some innate immune cells use antigen receptors.
- Dendritic cells sense both tissue-specific factors and innate immune stimuli in shaping T cell responses to antigens.
- Gut microbes that alter T cell differentiation increase susceptibility to joint inflammation and specific gut microbiota signatures are associated with new-onset rheumatoid arthritis.

The adaptive immune system is so named because it can adapt to virtually any pathogen or toxin that enters the body. Although invertebrates defend themselves through innate immunity alone,[1] all vertebrates have developed some form of adaptive immunity—that is, the ability to generate novel receptors by genetic recombination mechanisms that can then be selected to recognize diverse macromolecules associated with rapidly evolving pathogens.[2] A molecule that can be recognized by the adaptive immune system is known as an "antigen" (Table 18-1).

The ability to produce molecules and cells that can attack any biologic structure is a double-edged sword.[2] Although pathologic autoimmunity is not described in invertebrates, which evolved with a hard-wired immune system, it is a common problem in vertebrates.[3] Self-recognition must be offset by redundant mechanisms to produce self-tolerance. We discuss some mechanisms involved in this process and the anatomy behind these mechanisms in this chapter. In addition to self-antigens, animals with adaptive immunity are also exposed to many harmless environmental antigens that have the potential to induce allergic reactions.[4] Mechanisms to distinguish self-macromolecules from foreign macromolecules, as well as benign foreign macromolecules from harmful foreign macromolecules, are critical processes in successful adaptive immunity. At the core of these mechanisms is the essential partnership of adaptive and innate immunity, which was first formulated by Charles Janeway, Jr.[5] Although the adaptive immune system can recognize any foe and focus powerful effector mechanisms to destroy this foe, its ability to calculate the relative risks of mounting an immune response or becoming tolerant to a given recognized structure is guided by innate recognition of pathogen-associated molecule patterns (PAMPs) or inflammation triggered by tissue damage–associated molecular patterns (DAMPs).

The function of the adaptive immune system is tightly linked to its anatomy.[6,7] In some respects, T lymphocytes are cells without boundaries that can be found in almost any tissue at any time. T and B lymphocytes are readily monitored in patients because they are reliably found in the blood of healthy persons. However, the vast majority of the T and B lymphocytes are located in secondary lymphoid tissues, where they search for antigens. Three types of tissues concentrate lymphocytes: primary lymphoid tissues, where these cells are born; secondary lymphoid tissues, where they search for antigens and initiate immune responses; and tertiary lymphoid tissues that form at sites of chronic inflammation. Secondary and tertiary lymphoid tissues have a characteristic and functionally important organization into B cell and T cell zones. In fact, all of the previously mentioned histologic findings are directly related to functional goals of the adaptive immune system, as will be clarified subsequently.

This chapter addresses the basic concepts of adaptive immunity and its partnership with innate immunity in the context of the anatomic sites in which these responses take place.

## LYMPHOCYTE MIGRATION PARADIGMS FOR HOMING, INTERSTITIAL NAVIGATION, AND EGRESS

Because we talk about adaptive immunity in the context of secondary lymphoid tissues, it is worthwhile to first review what is known about lymphocyte migration. Since the early 1960s it has been appreciated that lymphocytes "recirculate" between secondary lymphoid tissues and the blood, and more recently we have learned that, upon activation, they take on different tissue-specific homing properties that are important for function.[8] If one arbitrarily begins this circuit with a naïve T cell in the blood, then three distinct transitions can be considered: (1) interaction with the vessel wall and extravasation; (2) interstitial locomotion in the tissue parenchyma; and (3) egress from the tissue parenchyma back into the blood, sometimes via lymph. General

**TABLE 18-1** Terms and Definitions

| Term | Definition |
|---|---|
| Antigen | Any molecular structure recognized by the adaptive immune system; the ligand for B cell receptor (BCR)/antibody or T cell receptor (TCR) |
| Chemokine | Family of small secreted or shed proteins (typically 8 kDa) that bind to G protein–coupled receptors and activate or attract cells; a chemical *(chemo-)* that induces movement *(-kine)* |
| Integrin | Family of adhesion molecules that are specialized for adhesion in the context of migration and generation of contractile force/mechanical stabilization; noncovalent heterodimers that are regulated rapidly by signaling from chemokine receptors and antigen receptors |
| Selectin | Family of adhesion molecules that are specialized for mediating initial attachment of leukocytes to the vessel wall from flowing blood; they have amino-terminal calcium-dependent lectin domains and interact with carbohydrate ligands that can incorporate protein determinants |

features of these three steps are addressed here, and relevant details will be commented on in different functional contexts in relation to adaptive immunity.

## Multistep Paradigm for Extravasation

The movement of lymphocytes from blood to tissues is complicated by the high-flow rates in blood vessels. Springer, Butcher, and colleagues[9-15] established the current paradigm called the *multistep model* for T cell extravasation.

The first step is the initial tethering of the free-flowing leukocyte to the vessel wall. A special class of adhesion molecules known as selectins and their carbohydrate ligands mediate this step (see Table 18-1).[10] The selectin family comprises three members: L-, E-, and P-selectin. L-selectin is expressed on naïve T and B lymphocytes and is essential for the entry of these cells into lymph nodes, but not into the spleen.[11] The ligand for L-selectin is a complex of sulfated sialic acid bearing complex carbohydrates linked to different protein backbones expressed on high endothelial cells in postcapillary venules in primary, secondary, and tertiary lymphoid tissues.[10] The distinctive morphology of these endothelial cells was first noted by Gowans and colleagues[8] and is due to the large number of transmigrating lymphocytes that distend the otherwise flat cells. E- and P-selectin are expressed on activated endothelial cells at sites of inflammation in diverse tissues.[12] They bind to glycoprotein ligands expressed on leukocytes that have terminal sialyl Lewis-X blood group antigens and can also incorporate other structural modifications.[13] The high-affinity ligand for P-selectin is the protein backbone P-selectin glycoprotein-1 (PSGL-1) with a stretch of sulfated tyrosines that make up part of the ligand. PSGL-1 can be expressed by lymphocytes without the necessary secondary modification to make it a ligand for P-selectin. Therefore a fusion of P-selectin to immunoglobulin Fc that can be purified and fluorescently tagged is the best probe to determine if a leukocyte is competent to bind to P-selectin–expressing endothelial cells. The genetic basis of forming selectin ligands is complex with requirements for expression of core proteins, specific sialotransferases, fucosyltransferases, and sulfotransferases.[13] Defects in fucose metabolism are the basis for a rare genetic immunodeficiency/mental retardation syndrome called *leukocyte adhesion deficiency type 2* (LAD2).[14] Selectins will only mediate leukocyte tethering and rolling, not arrest and extravasation.

Selectin-mediated tethering allows the leukocyte to bring G protein–coupled receptors close enough to the vascular wall to bind ligands attached to glycoproteins.[15] Chemokine receptor signaling is critical to activate closely linked integrin family members to bind their ligands.[16] This chemokine signal is pertussis toxin–sensitive, indicating that it involves $G_{i\alpha}$-coupled receptors. Three chemokine receptors are important with respect to lymphocyte recirculation: CCR7, CXCR4, and CXCR5. CCR7, which binds to ligands CCL19 and CCL21, is the most important chemokine system for entry of T cells into secondary lymphoid tissues.[17] The binding of CXCR4 to its ligand CXCL12 also contributes to entry of T and B cells.[18] The binding of CXCR5 to its ligand CXCL13 is the major system that controls entry of B cells into secondary lymphoid tissues.[19] After activation, CCR7 is downregulated on many effector T cells and other chemokine receptors are upregulated, allowing these cells to home to peripheral sites of inflammation.[20] Activated endothelial cells in these tissues express ligands that selectively recruit subsets of activated T cells. In contrast, activated B cells either become memory cells that retain CXCR5 and CCR7 expression[21] or differentiate into plasma cells that downregulate CXCR5 and CCR7 and upregulate CXCR4, targeting these cells to medullary cords via a novel migratory mechanism and bone marrow.[22]

Integrin family members are the immediate recipients of chemokine signals to produce rapid arrest of rolling leukocytes and initiate the extravasation process.[16] The major integrin that mediates homing to secondary lymphoid tissues is leukocyte function–associated antigen 1 (LFA-1), which is composed of the αL and β2 subunits. LFA-1 is expressed only on leukocytes and binds to intercellular adhesion molecules (ICAMs), of which the best characterized are ICAM-1 and ICAM-2.[23] ICAM-1 and ICAM-2 are the major ICAMs expressed on endothelial cells, with ICAM-1 displaying regulated expression in response to inflammatory mediators like tumor necrosis factor (TNF) and interferon (IFN)-γ.

The deficiency of the integrin β2 subunit is the basis of a rare genetic syndrome known as *leukocyte adhesion deficiency type 1* (LAD1). In this disease, leukocyte extravasation at sites of inflammation is defective and patients are highly susceptible to bacterial infections of the skin and mucous membranes. Patients with LAD1 are developmentally normal and can be treated by bone marrow transplantation with a high success rate.[24] A leukocyte adhesion deficiency type 3 in which multiple leukocyte integrins show defects in regulation of Rap1, a small G protein important in LFA-1 regulation, has also been described.[25]

The structure of integrins reveals remarkable machinery for regulated adhesion.[26] The inactive form is folded into a compact globular structure, in which the ligand-binding domain points toward the leukocyte surface. After activation by chemokines, the integrin extends to two times its original height and projects the ligand binding site to greater than 20 nm from the leukocyte membrane, with orientation toward the endothelial cell surface.[27] This

dramatic change is closely coupled to cytoskeletal association, providing the anchorage needed for arrest and cell spreading after ligand binding.[28]

A second integrin expressed on naïve and activated lymphocytes, very late activation antigen-4 (VLA-4), is composed of the α4 and β1 subunits; it can play a small role in entry into lymph nodes but a major role in entry into inflamed sites. Its ligand is vascular cell adhesion molecule (VCAM), which is also a member of the immunoglobulin superfamily regulated by inflammatory cytokines.[29] Inhibition of VLA-4 by a monoclonal antibody (natalizumab) is the basis of an approved treatment for multiple sclerosis that decreases leukocyte entry into the central nervous system.[30] Natalizumab therapy has been associated with rare cases of progressive multifocal leukoencephalopathy, a severe infection caused by reactivation of latent John Cunningham (JC) virus.[31] Thus risks and benefits need to be weighed carefully with immunosuppressive therapies even when only a single specific pathway is targeted. When T lymphocytes are activated to home to mucosal effector sites, they upregulate expression of the integrin β7 (which also associates with α4 to form the gut-homing integrin α4β7) and bind a different immunoglobulin superfamily ligand called MAdCAM (i.e., *m*ucosal *ad*dressin cell *a*dhesion *m*olecule), which is expressed on endothelial cells in the gut.[32]

The extravasation process involves the movement of lymphocytes between or through endothelial cells.[33] Endothelial junctional complexes include special adhesion molecules that need to be transiently disengaged to allow lymphocyte passage between endothelial cells. The transcellular pathway may be dominant in situations in which the endothelial junctions are particularly sturdy, as in the brain, thymus, or lymph nodes. Both junctional and transcellular routes involved active processes in the leukocyte and endothelial cells, but this step is not thought to be regulated to control homing decisions.

To summarize, three types of receptor ligand pairs define the key regulated steps in lymphocyte homing. The compatibility of all three is required to gain entry into the tissue. If a compatible selectin-ligand pair is not available, the leukocyte will not be able to initiate adhesion to the endothelial wall and will flow past. If a chemokine receptor-chemokine pair is not available, it will be impossible to activate integrins, even if the selectin-ligand pair mediates rolling or tethering, and the cell will eventually release and remain in the blood. If the integrin-ligand pair is not compatible, the cells will not be able to arrest and extravasate, even if the selectin-ligand pair and chemokine-ligand systems are engaged. Thus these molecular pairs can be thought of as a hierarchic area code for lymphocyte homing, with the digits defined by the compatible interactions, each of which must be correctly engaged to allow entry.[34]

## Tissue Organization and Interstitial Migration

Classical histology and mouse genetics have been used to establish the molecular mechanisms that account for the segregation of T cells and B cells within secondary lymphoid tissues. The T cell zone is defined by the production of CCL19 and CCL21 by stromal cells and the expression of CCR7 on T cells.[17] Interestingly, these signals are the same ones that trigger the arrest of T cells on endothelial cells for tissue entry. T cell zones are also amply populated by conventional dendritic cells (DCs), which express CCR7 as they mature. DCs appear to form a network on a scaffold of reticular fibers.[35] The parenchyma of lymph nodes and splenic white pulp nodules are crisscrossed by thick collagen bundles sheathed in fibroblastic reticular cells.[36] The inner compartment of these fibers forms a network of conduits in the lymph node and spleen that allows DCs in the parenchyma access to the afferent lymph or blood, respectively. The B cell follicles depend on CXCL13 expressed by follicular stromal cells and CXCR5 expressed on B cells. In fact, the balance of CXCR5 and CCR7 expression by B cells controls their proximity to the boundary between T cell zone and B cell zone, where B cells can encounter T helper (Th) cells.[21] B cell zones are also populated by variable numbers of follicular DCs, which are differentiated stromal cells rather than cells of hematopoietic origin.

Two-photon laser scanning fluorescence microscopy has revealed the dynamics of immune cells in secondary lymphoid tissues. Fluorescently labeled T cells moved with an average speed of 12 μm/min in T cell zones, and B cells moved 30% slower in the follicles of acute organ-cultured lymph nodes of live mice.[37] The paths taken by T and B cells appeared random, but subsequent analysis of fluorescent lymphocyte movement in the presence of differentially labeled stromal cells revealed that the lymphocytes were guided by a ramified stromal network and changed direction frequently as they encountered branches in the stromal scaffolding.[38] The DC network is supported by the stromal network, ensuring that T cells contact DCs as they follow a random pathway through the stromal network.[35] Thus the process by which a DC that has brought antigen from the periphery can show this antigen to many T cells is based on forming random contacts with thousands of T cells per hour. Because of its random nature, this model has been referred to as "stochastic repertoire scanning."

The major signal that stimulates the rapid and random migration of T and B cells in lymph nodes is thought to be chemokines presented on the surface of stromal cells. The speed of B lymphocyte migration is significantly reduced in mice lacking $G_{i\alpha 2}$ subunit of G protein–coupled receptors, further supporting the model that chemokines may have a role in this process.[39] Chemokines can act as chemoattractants but can also stimulate migration in a random fashion—called *chemokinesis*—under some conditions. Rapid T cell motility in vitro can be recapitulated by surfaces coated with only CCR7 ligands.[40] Somewhat surprisingly, integrins such as LFA-1 contribute little to the migration speed of DCs or T cells.[40,41]

Although the initial scanning process is random, once antigen-bearing DCs begin to interact with antigen-specific T cells, a number of nonrandom elements of migration are established. B cells that recognize antigen upregulate CCR7 and downregulate CXCR5, such that they are attracted to the boundary between the T and B cell zones.[21] DCs that have been in contact with $CD4^+$ T cells produce CCL3 and CCL4, which attract $CD8^+$ T cells under inflammatory conditions.[42] This directed migration of $CD8^+$ T cells biases the scanning of the $CD8^+$ T cell repertoire toward DCs that have received T cell help and thus have come into contact with interesting antigens. This process likely increases the efficiency of repertoire scanning.

### Immunologic Synapses Maintain Antigen-Specific Interactions with Dendritic Cells

The most extreme change in lymphocyte migration during an immune response is the near full arrest referred to as an *immunologic synapse*.[43] In vitro analysis has revealed that underlying the arrest of T cell migration are elaborately organized structures that are in contact with DCs bearing appropriate MHC-peptide complexes.[44] In vivo imaging analysis has repeatedly revealed stable T cell–DC interactions as a common feature of both tolerance and immunity induced by high-affinity ligands.[45] Although LFA-1–ICAM-1 interactions are not necessary for migration in lymph nodes, these adhesion molecules are required for stable synapses.[46] Immunologic synapses have been proposed to lead to asymmetric cell divisions that generate effector T cell and memory T cell precursors.[47] Another possibility is that stable immunological synapses during priming are related to delivery of premitotic effector functions involving regulatory cytokines such as interleukin (IL)-2.[48] Dynamic T cell–DC interactions referred to as *kinapses* may set up symmetric divisions that help maintain the differentiated state of these early precursors.[49]

### Egress from Lymph Nodes and the Thymus: Sphingosine 1 Phosphate

The recirculation of lymphocytes requires that they periodically cease their local scanning activity or activation process in secondary lymphoid tissues and exit to the lymph or blood, which is referred to as *egress*. Egress is also important for recently matured lymphocytes as they leave the bone marrow or thymus to move to secondary lymphoid tissues. Insight into the molecular processes controlling egress from lymph nodes and the thymus were provided through investigation of the fungal metabolite derivative FTY720, which has been approved as a drug (fingolimod) for treatment of relapsing-remitting multiple sclerosis.[50] FTY720 administration rapidly decreases T and B cell numbers in blood. FTY720 is phosphorylated by sphingosine kinase and acts as an agonist for a number of sphingosine 1 phosphate receptors that are expressed on lymphocytes and endothelial cells. Further insight was provided by the study of bone marrow chimeric mice in which fetal liver cells from embryonic lethal sphingosine 1 phosphate receptor 1 (S1PR1) knockout mice were used to reconstitute lethally irradiated syngeneic wild type mice.[51] The S1PR1-deficient, recently matured lymphocytes are unable to exit the thymus. Furthermore, when the mature S1PR1-deficient lymphocytes trapped in the thymus were transferred into wild-type recipients, they were able to enter lymph nodes normally but could not egress from lymph nodes because of failure to counterbalance CCR7-dependent retention signals. These results suggested a T cell autonomous defect in egress from both the thymus and lymph node. Although FTY-720-P is an agonist of S1PR1, it has the effect of downregulating expression of the receptor such that the compound recapitulates the knockout phenotype. A parallel study with reversible S1PR1 agonists and antagonists suggests that S1PR1 also has a role in controlling lymphatic endothelium permeability, and this effect would contribute to arrest of egress in a similar manner to the T cell autonomous effects.[52]

## PRIMARY LYMPHOID TISSUES: SITES WHERE T AND B CELLS ARE GENERATED AND SELF-TOLERANCE MECHANISMS ARE INITIATED

The critical event in the birth of T and B cells is the rearrangement of the antigen receptor genes to generate T cell antigen receptors (TCRs) and B cell antigen receptors (BCRs) that are expressed on the cell surface. Each T cell and B cell has a single antigen receptor as birth certificate and identification card. The life, death, or expansion of each of these cells controls the availability of this antigen-binding structure to the adaptive immune system. This is the heart of the clonal selection theory first proposed by Burnett in the 1950s. Self-reactive cells need to be deleted or retasked shortly after their birth. This process takes place in the bone marrow for B cells and in the thymus for T cells. The anatomy of these two sites is different, in keeping with the dramatically different recognition mode employed by B and T cells. First I will discuss the bone marrow space, followed by the functional anatomy of the thymus.

### B Cell Development in the Bone Marrow

Immature B cells express surface BCRs composed of surface immunoglobulin (Ig) noncovalently complexed to the signal transducing subunits Ig$\alpha$ and Ig$\beta$[53] (see also Chapter 13). The majority of immature B cells are reactive to self-antigens and even display "polyreactivity," meaning that they produce antibodies that bind not just one but many self-antigens.[54] These autoreactive cells are mostly lost from the repertoire in two checkpoints—the encounter of immature B cells with antigens in the bone marrow or by newly matured B cells upon entry into secondary lymphoid tissues.[54] Checkpoint 1 depends on antigen display in the bone marrow. If BCRs on immature B cells encounter surface immobilized antigens on bone marrow cells or extracellular matrix, they will undergo apoptosis. The second source of self antigens is the blood. The bone marrow parenchyma is bathed in blood plasma antigens due to fenestrated endothelial cells lining bone marrow sinusoids. When soluble antigens bind to their BCRs, they may undergo apoptosis if the antigen is multivalent and cross-links the BCR, inducing strong signaling. If the antigen is monovalent, the B cell may become anergic—a form of nonresponsiveness that is induced by weaker signaling through the BCR. In the second checkpoint, newly matured B cells that have egressed from the bone marrow will encounter antigens on a variety of cells. For example, DCs present intact antigens to B cells,[55] and because DCs sample many tissue antigens, this may provide a wider array of tissue-specific self-antigens to check against the BCR. These selection checkpoints decrease the frequency of self and polyreactive B cells by greater than 10-fold, but some polyreactive B cells persist in the repertoire. Polyreactivity may contribute to pathogen recognition, as was recently shown for neutralizing antibodies to low-density envelope glycoprotein of HIV.[56] Thus the adaptive immune system may always need to tolerate some self-reactivity to defend us against the universe of pathogens.

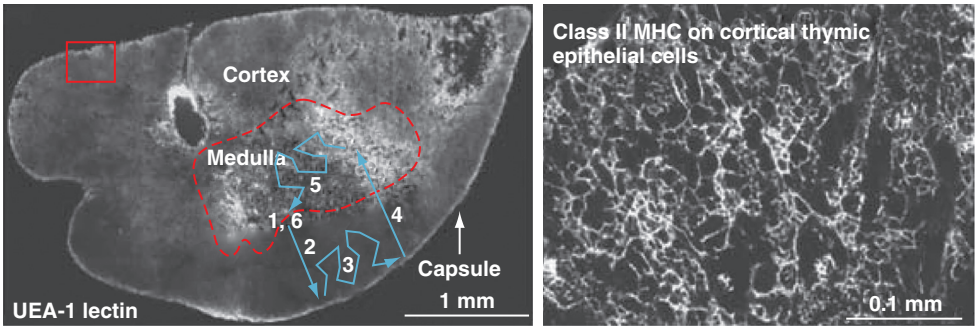

**Figure 18-1** Section of mouse thymus stained with *Ulex europeus* antigen-1 (UEA-1) lectin *(left)* or anti–class II major histocompatibility complex (MHC) *(right)* visualized with immunofluorescence microscopy. The UEA-I staining is strongest in the medulla but also highlights the capsule and stroma of the cortex. The cortical thymic epithelial cells are strongly positive for MHC molecules, which allow negative and positive selection of thymocytes. The *blue arrows* indicate a hypothetical path of a developing T cell (thymocyte) through the thymus: (1) entry via the corticomedullary junction, (2) migration into the cortex, and (3) scaffolded random walk in the cortex during which positive or negative selection can take place; (4) if positive selection takes place, the thymocyte undergoes directed migration to the medulla where negative selection or conversion into a thymic regulatory T cell (see below) remains possible; (5) the mature single positive thymocyte migrates back to the corticomedullary junction and (6) egress under control of sphingosine-1 phosphate mediate chemotaxis. *(Images courtesy Richard Lewis, Stanford University.[57])*

## T Cell Development in the Thymus

T cell precursors arrive in the thymus and initiate TCR gene rearrangement in this microenvironment (see also Chapter 12). The thymus is an epithelial organ formed during development from the third pharyngeal arch. Histologically, the tissue has a clearly distinguishable cortex, medulla, and vascular corticomedullary junction.[7] Figure 18-1 is adapted from a recent article examining the dynamics of T cell selection in the thymus.[57] It shows fluorescence staining with *Ulex europeus* antigen-1 (UEA-1) lectin, a marker for the thymic medulla, on the left side and class II major histocompatibility complex (MHC) antigen in the thymic cortex on the right side. The stepwise path of thymocyte migration is outlined in the left panel. Early $CD4^-$ and $CD8^-$ progenitors enter via postcapillary venules at the corticomedullary junction (step 1) and migrate to the subcapsular region of the cortex, where TCR gene rearrangement takes place and CD4 and CD8 become expressed on the surface of immature T cells, also called *thymocytes* (step 2). These cells then migrate randomly among thymic epithelial cells in the cortex, sampling self-MHC-peptide complexes (step 3). If they express a TCR that recognizes self-MHC-peptide complexes with low affinity, they will undergo "positive selection." Positively selected thymocytes then mature into $CD4^+$ or $CD8^+$ cells that migrate to the medulla under control of CCR7 ligands[58] (step 4). Medullary thymic epithelial cells express a transcription factor called *AIRE* that mediates expression of a number of tissue-specific genes by amplifying expression from poorly expressed chromatin regions.[59] A small number of persons lacking expression of AIRE have a complex autoimmune syndrome characterized by polyendocrinopathy and other tissue-specific autoimmune diseases. The hypothesis is that AIRE-mediated transcription of otherwise tissue-specific genes in thymic epithelial cells promotes negative selection of some autoreactive T cells and may also promote generation of tissue antigen-specific regulatory T cells (step 5). Conventional positive selection requires Ras activation on intra-cellular membranes, whereas stronger Ras activation at the plasma membrane mediates negative selection.[60] Regulatory T cell generation requires signaling through protein kinase C-θ and c-Rel transcription factors.[61] The small percentage of thymocytes that express a TCR and pass both positive and negative selection downregulate CD69 and S1PR1 and exit the lymph nodes as naïve "conventional" T cells (step 6).

## SECONDARY LYMPHOID TISSUES: SITES WHERE ANTIGEN FINDS RARE SPECIFIC T AND B CELLS

The frequency of naïve T cells that recognize any particular antigen is so low that it has been challenging to estimate. Recently, enrichment methods using antibody-coated magnetic beads have been developed to assist direct measurement of precursors by flow cytometry with high-avidity MHC-peptide–based probes known as *tetramers*.[62] The number of cells specific for commonly used model antigens is approximately 500 in most mouse strains when pooling cells from all secondary lymphoid tissues (spleen and lymph nodes). Approximately 500 million total $CD4^+$ T cells are present in these tissues, and thus antigen-presenting DCs need to make contact with a million irrelevant T cells to find one specific T cell. Thus a small number of antigen-positive DCs early in an infection must have access to highly concentrated swarms of T cells in secondary lymphoid tissues to sample enough T cells to find a few specific precursors to activate and expand. As described earlier, this search process is initially random but may become more directed and efficient as a response progresses. Although naïve T cells recirculate in an unbiased manner through secondary lymphoid tissues, the antigen-carrying cells, primarily DCs, have a high degree of regional bias in their movement, such that they are thought to relay information about both innate immune stimulation and tissue of origin of antigens to T cells.

Once antigen-specific T cells come into contact with antigen-bearing DCs, they initially form synapses with multiple DCs to (1) integrate signals through the T cell receptors and co-stimulatory ligands (which represents part of the innate immune system's contribution to T cell activation) and (2) form more stable synaptic interactions to deliver early effector cytokines to DC and other T cells; they then

divide more than 20 times with short cell cycle times of approximately 6 hours.[63] Expansion of $CD8^+$ T cells, which give rise to cytotoxic effector cells, is greater in general than for $CD4^+$ T cells, which give rise to various types of Th cells. After expansion, which peaks around day 7 to 10, the infectious agent is often eradicated and most of the effector T cells undergo apoptosis. The flulike symptoms associated with viral infections are due to cytokines produced by the dividing and differentiating T cells.

Because primary adaptive responses take a week or longer to develop, the host is dependent on innate immune mechanisms like natural antibodies, neutrophils, interferons, and natural killer (NK) cells to control the infection until sufficient numbers of effector T cells are generated. Thousands of the expanded T cells that survive after the pathogen is destroyed become memory cells.[64] Although the process of asymmetric division may contribute to the establishment of memory and effector cells, models in which events cannot be attributed to a single asymmetric first division but must incorporate additional stochastic events that have an impact on the lineages of multiple precursors are required to account for results in in vivo fate mapping experiments.[65]

There are two subsets of memory T cells: (1) central memory cells that express L-selectin, CCR7, and high LFA-1 and recirculate via secondary lymphoid tissues, and (2) effector memory cells that lack L-selectin and CCR7 but may express P- and E-selectin ligands and other chemokine receptors such as CXCR3, CCR5, CCR4, and/or CCR9.[66] Macrophages in the subcapsular sinus of lymph nodes produce CXCL9, which recruit $CXCR3^+$ memory T cells into the interfollicular area, where they are positioned to intercept incoming DCs as they move through the subcapsular sinus into the T cells zones.[67] Effector memory cells largely migrate to peripheral sites of inflammation and are equipped for rapid effector function if they encounter antigen. Memory cells respond rapidly to recurrence of the same infection, and together with antibodies, they rapidly eradicate that same agent if it is encountered a second time. These memory cells may also cross-react with other pathogens, and depending on the degree of cross-reaction, this type of response can result in rapid clearance of a new pathogen or, sometimes, an impaired response.

## Antigens from Blood Are Detected Most Efficiently in the Spleen and Liver (Portal System)

The spleen is a large visceral organ that filters approximately 5% of the cardiac output. The red pulp is an important location for removal of aged red blood cells from the circulation. The red pulp also contains many macrophages that specialize in this clearance process,[68] as well as DCs that come into direct contact with naïve T cells in the blood. The function of these red pulp DCs is not known. Most attention has been focused on the white pulp nodules and the marginal zone as sites of T cell–DC interaction and antigen capture, respectively (Figure 18-2, *left*). Blood flows into the spleen via an artery that splits into arterioles that empty into venous sinuses in the marginal zone and red pulp (Figure 18-2, *right*). The blood is then re-collected into a venous system that drains to the liver, joining with the portal tract. The arterioles are surrounded by sheaths of T cells (the periarterial lymphoid sheath [PALS]) that make up the T cell zones of the white pulp. Bridging channels connect the red pulp, where lymphocytes leave the blood, to the PALS, where they migrate in a pertussis toxin–sensitive manner.[69] B cell follicles and the marginal zone

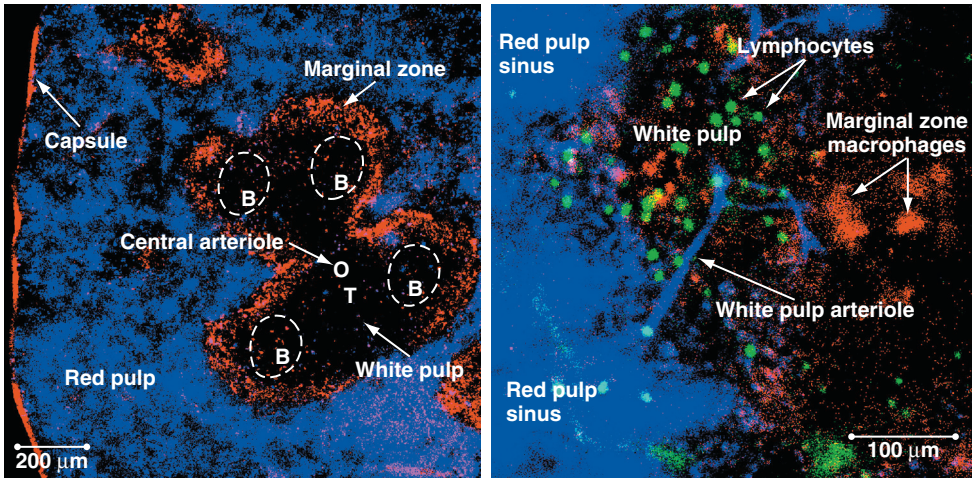

**Figure 18-2** Organization of the spleen. *Left,* Tissue section from a mouse injected with low-molecular-weight *(blue)* and high-molecular-weight *(red)* fluorescent dextrans. The low-molecular-weight dextran labels the red pulp *(blue)* and the high-molecular-weight dextran labels macrophages in the marginal zone *(red)* such that the white pulp nodule, which contains approximately $10^9$ lymphocytes per $cm^3$, is dark. The white pulp nodule forms around a central arteriole (O) from which smaller arterioles branch to the red pulp sinuses. B and T cells are segregated into follicles (B) and the periarteriolar lymphoid sheath (T). (Scale bar 0.2 mm.) *Right,* Image of a live mouse spleen during injection of low-molecular-weight fluorescent dextran. The blood carrying the dextran passes through the white pulp in small blood vessels *(arrows)* emanating from the central arteriole (not shown) and connected to red pulp sinuses that rapidly fill with blood, which fills the marginal sinus but not the white pulp itself. In this image approximately 0.3% of the T cells in the PALS are labeled with a fluorescent dye. These areas are packed with T and B cells. Marginal zone macrophages and B cells have direct access to blood to capture pathogens. White pulp lymphocytes are not in direct contact with blood and need antigen presentation by cells that migrate from the marginal zone or antigens that are delivered to dendritic cells via reticular fibers.[108] (Scale bar 0.1 mm.) *(Courtesy Janelle Waite, New York University.)*

then surround the PALS. Macrophages, DCs, and marginal zone B cells line the marginal zone, where they have direct access to blood antigens. DCs that pick up antigens in the marginal zone migrate to the PALS within 9 hours.[70] A reticular fiber network connects the marginal zone to the PALS and allows soluble antigens from the blood to reach resident DCs in the PALS. Thus the spleen provides multiple opportunities to mount primary and recall responses to particulate or soluble antigens in the blood.

As mentioned earlier, venous blood from the spleen drains into the liver. Immune responses in the liver are poorly understood, but this site is important because many pathogens colonize the liver. Two blood circulations supply the liver: the portal vein with deoxygenated blood from the gut and spleen, and the hepatic artery with oxygenated blood. These circulations mix in the liver sinusoids, a low-pressure network of blood spaces between sheets of hepatocytes connecting the portal tract and the central collecting vein. Thus most of the liver parenchyma appears as plates of hepatocytes alternating with blood-carrying sinusoids (Figure 18-3, *left*). The liver is rich in a type of sessile macrophage called a *Kupffer cell* and patrolling lymphocytes, particularly NK T cells in the mouse and mucosal-associated invariant T (MAIT) cells in humans (Figure 18-3, *right*).[71,72] Both of these cell types participate in antibacterial immunity. The major antigen-presenting cells in the liver are not Kupffer cells but the perivascular Ito cells.[73] The liver also plays an important role in the clearance of B cells mediated by therapeutic anti-CD20 antibodies that are used to treat patients with rheumatoid arthritis.[74]

## Antigens from Mucosal Surfaces Are Detected Most Efficiently in Peyer's Patches and Mesenteric Lymph Nodes

The mucosal-associated lymphoid tissues include the tonsils, Peyer's patches, lamina propria, cryptopatches, and appendix. Peyer's patch and lamina propria DCs have different mechanisms for sampling the contents of the gut lumen. Peyer's patches are composed of large B cell follicles with smaller T cell zones (Figure 18-4, *top* and *bottom right*). They have high endothelial venules that allow efficient entry of naïve T and B cells, as well as memory cells with gut homing phenotypes. The large size of the follicles in the Peyer's patches causes a domelike effect with the epithelium protruding into the lumen. Smooth-surfaced M cells replace some of the microvilli-laden absorptive epithelial cells in this dome region of Peyer's patches. These cells act as relay points for entry of enteric pathogens into the dome region of Peyer's patches, where a population of $CCR6^+$ DCs efficiently presents pathogen-related antigens to induce rapid local T cell responses[75] (Figure 18-4, *bottom left*). In contrast to the Peyer's patches, activated T cells, plasma cells, DCs, and macrophages populate the core of the villi in the terminal ileum. The DCs migrate to mesenteric lymph nodes, where they present antigens to stimulate production of regulatory T cells and effector T cells to balance gut tolerance and immunity.[76] $CX3CR1^+$ macrophages actively sample the gut contents and then may present antigens to effector and regulatory T cells that patrol the lamina propria[77] (Figure 18-4, *bottom left*). The gut presents a barrier between the host and billions of commensal bacteria and food antigens. There are also many pathogens, such as bacteria, viruses, protozoans, and worms, that exploit this niche. Recently it has been found that new-onset rheumatoid arthritis is associated with expansion of particular microbial taxa in the gut.[78] This area of research is rapidly developing and is touched on again in the context of T cell differentiation.

## Antigens from Other Tissues and Solid Organs Are Detected in Peripheral Lymph Nodes

An extensive network of peripheral lymph nodes filters lymph from the skin, visceral organs, and nervous system. Lymph is composed of fluid that leaves blood vessels and

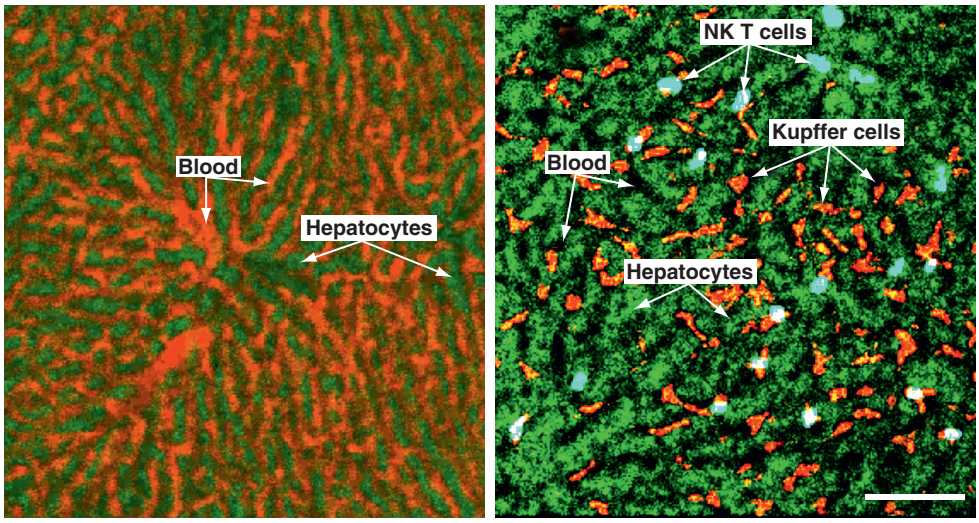

**Figure 18-3** Microcirculation and immune cells in liver. *Left,* Intravital imaging of blood space in mouse liver. Confocal imaging of hepatocytes (green autofluorescence) and blood space (red fluorescent dextran) is shown. The flow pattern is toward the center of the image panel. *Right,* Intravital imaging of natural killer T (NK T) cells (blue-green) and SIGN $R1^+$ Kupffer cells in liver sinusoids (dark spaces) between hepatocytes (green autofluorescence). The DCs extend processes through the epithelial layer to assist uptake of luminal antigens (*arrows* in bottom right point to the DC projections in the gut lumen).[110]

then must be collected from the tissues in afferent lymphatic vessels, passes through at least one lymph node, exits the lymph node as efferent lymph, and is returned to the blood via the thoracic duct. The afferent lymphatics of a lymph node connect to the capsule of the node and drain into the subcapsular sinus, which contains many macrophages (Figure 18-5). The floor of the subcapsular sinus covers the lymph node parenchyma and is the point of origin of the reticular fiber network that connects to the high endothelial venules and medullary cords, where cells move from the parenchyma into the efferent lymph. Lymph does not come into direct contact with cells in the parenchyma, but cells lining the reticular fibers and a space between the high endothelial venules and the reticular fibroblast sheath are exposed to lymph fluid.[36] The parenchyma is divided into T and B cell zones defined by distinct populations of stromal cells producing CCL19/21 and CXCL13, respectively (see Figure 18-5). DCs migrate from peripheral tissues in a CCR7-dependent manner and join networks of DCs in the T cell zones with scattered cells in the follicles.[35] Emigrant DCs have been reported to array around high endothelial venules, where they are efficiently encountered by newly extravasated T and B cells. In experimental models, antigen-positive DCs have been shown to stop both B and T cell migration during antigen encounters.[45,55] These immunologic synapses, discussed earlier, play an important role in antigen transfer for B cells and for priming of the proliferative response in T cells. It has been noted that different populations of DCs such as dermal DCs and Langerhans cells actually populate different subregions of the T cell zones, but the significance of this phenomenon is not clear.

## Peripheral Tolerance Induction under Steady-State Conditions

Lymph nodes are associated with peripheral tolerance induction. The presentation of antigens in the steady state by DCs induces proliferation of T cells that are then deleted or anergic by 7 days.[79] This process may be particularly important to tissue-specific antigens that are not present in the thymus in the steady state.[80] It is known that low-affinity self-antigens can escape peripheral tolerance induction by this mechanism.[80] Low-affinity self-antigen–specific T cells that are then activated in the context of infection by a pathogen with strong innate stimulation may then induce tissue-specific autoimmunity.[80]

## Regulatory T Cells Reduce Autoreactivity by Inhibiting Immunologic Synapse Formation

Regulatory T cells are CD25$^+$ IL-2 dependent T cells that express the transcription factor FoxP3 and have the ability to suppress immune responses to tissue-specific self-antigens.[81] These cells represent another layer in redundant mechanisms to prevent autoimmune attack by adaptive immunity. One way in which regulatory T cells function is to block immunologic synapse formation between T cells and autoantigen-presenting DCs.[82] This mechanism appears to operate on low-affinity self-antigens that are the most

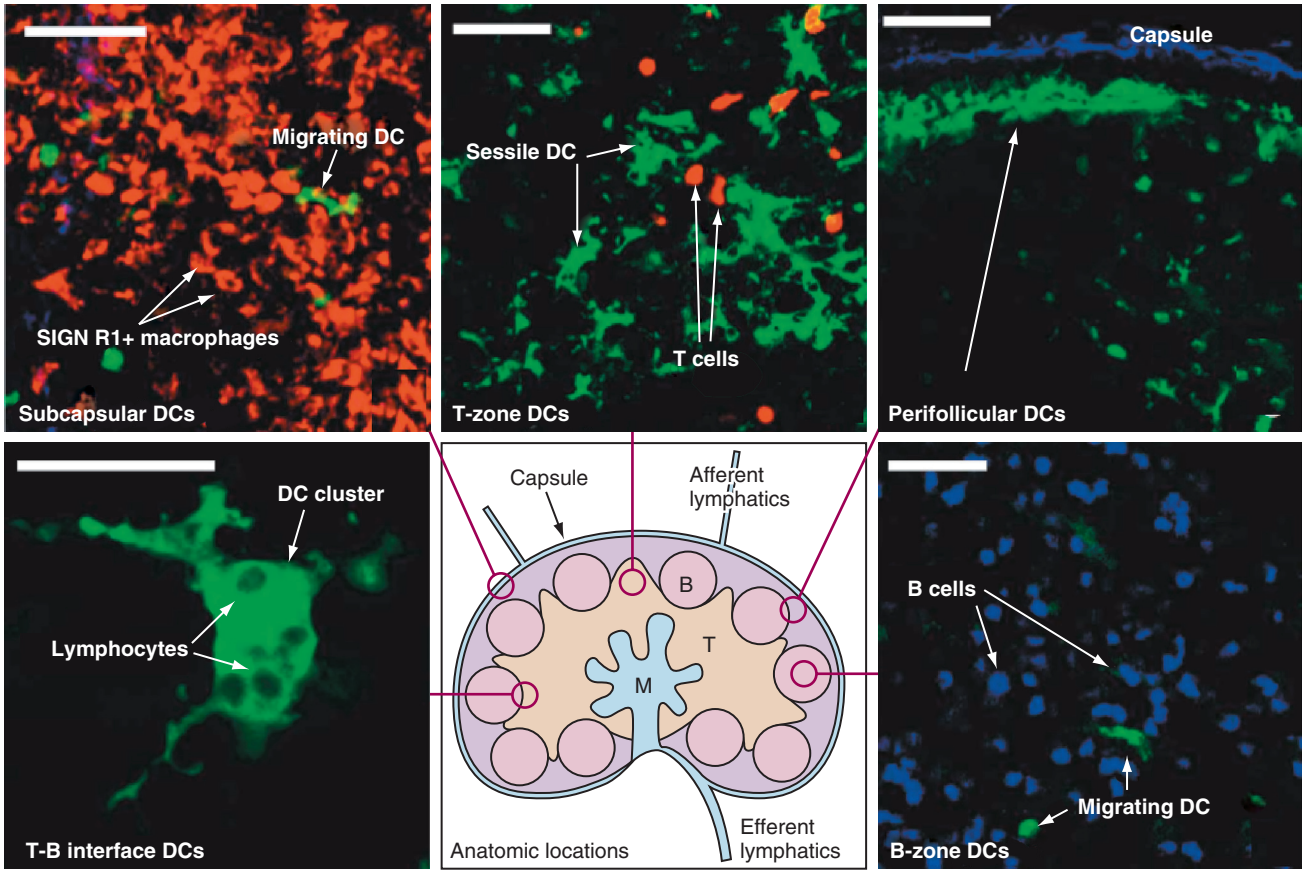

**Figure 18-5** Lymph node schematic and dendritic cell (DC) structures. Intravital microscopy–based images of DCs in lymph nodes of CD11c-YFP marker mice are linked to a schematic of the lymph node. (All scale bars 50 μm.) *Schematic:* Lymph enters via the afferent lymphatics and exits via the efferent lymphatics. T cells enter the lymph node via the high endothelial venules and exit via medulla to the efferent lymphatic. B, B cell follicles; M, medullary cords; T, T cell zone. *(From Lindquist RL, Shakhar G, Dudziak D, et al: Visualizing dendritic cell networks in vivo.* Nat Immunol *5:1243–1250, 2004.)*

likely type of self-reactive T cell to escape other peripheral tolerance mechanisms. Prevention of long-lived T cell–DC interactions may reduce proliferation and cytokine production by autoreactive T cells.

## Changes in the Lymph Node during Infection/Vaccination

Infection or vaccination in tissues induces a strong reaction in draining lymph nodes. Innate signals trigger production of inflammatory cytokines that lead to increased blood flow, increased adhesion molecule and chemokine expression to increase T and B cell entry, and suppression of T and B cell exit by downregulation of S1PR1.[83] DCs in reactive lymph nodes express higher levels of co-stimulatory ligands such as CD80 and CD86 and promote robust proliferation, survival, and differentiation of antigen-specific T cells. T cells that are activated in the lymph nodes regain expression of S1P1 after 3 to 4 days, along with a new repertoire of homing molecules, and migrate to effector sites.

## Tissue Environment of Immature Dendritic Cells Determines T Cell Imprinting

When T cells are activated in lymph nodes, the repertoire of homing molecules expressed by the activated effector T cells is determined in part by the origin of the DC.[84] DCs arise from a common monocyte-like precursor that migrates into tissues via the blood. DCs that drain from the gut produce retinoic acid from vitamin A. After maturation and migration to draining lymph nodes, these DCs secrete retinoic acid, which induce activated T cells to express gut-homing chemokine receptors like CCR9 and gut-specific integrins like α4β7. Because gut-associated postcapillary venules express MAdCAM and present CCL25 (a CCR9 ligand), these effector T cells tend to home to the gut. In the absence of retinoic acid produced by gut-derived DCs, the signals induced by skin-derived DCs favor expression of ligands for E- and P-selectin and CCR4 on T cells.[84] Because endothelial cells of skin-associated postcapillary venules express P-selectin and present CCL17, these T cells tend to home to inflamed skin. Recently, it has been shown that DCs in the skin metabolize vitamin D to generate a signal for T cell expression of CCR10, which allows these cells to migrate to the epidermis in response to CCL27. Although DCs will strongly skew T cells to home back to the sites from which the DCs migrated, the expression of homing receptors and chemokines on lymphocytes also has a stochastic component, which means that these effector cells and memory cells will also show up in diverse peripheral sites scattered throughout the animal—thus giving effector T cells their ability to appear in any tissue at any time.

Overall, these results show that DCs sense their tissue environment and innate immune activation signals in the process of shaping T cell responses.

## Germinal Center Reactions: Sites of Antibody Affinity Maturation and Class Switch Recombination

Low-molecular-weight antigens that enter the subcapsular sinus are directly accessible to B cells.[85] Particulate antigens are captured by subcapsular macrophages and transferred to B cells, which then mediate their transport to follicular dendritic cells in a nonantigen-specific process requiring complement receptors.[86] B cell activation by antigens in conjunction with co-stimulation via complement receptor or other forms of innate immune stimulation can lead to immediate proliferation of the B cells and the formation of plasma cells producing IgM antibodies from daughter cells.[87] A specific subset of follicular helper T (Tfh) cells promotes the formation of germinal centers within the B cell zone of any secondary lymphoid tissues in a manner critically dependent on the inducible T cell co-stimulator (ICOS).[88] Germinal centers are roughly spherical collections of hundreds of antigen-specific B cells that undergo interaction with Tfh cells in the light zone and proliferation in the dark zone[89] (Figure 18-6). The light zone is populated by stromal follicular DCs (which, unlike conventional DCs, are of nonhematopoietic origin) and Tfh cells. Follicular DCs use complement receptors to hold immune complexes on their surface for sampling by antigen-specific B cells. The Tfh cells provide help to B cells that maintain or increase their affinity for antigens and can also provide cytokine signals to promote class switching. Intravital microscopy studies demonstrate that germinal centers are dynamic open structures in which antigen-specific B cells are continuously in motion and follicular DCs are accessible to interaction with B cells that have diverse receptor specificity.[90] Thus antigen-specific B cells can be recruited into germinal center reactions at any time in the process and can compete openly with B cells that were present earlier.[91] Interactions between Tfh cells and centrocytes in the light zone are also highly dynamic and depend on the SLAM associated protein (SAP) adapter protein.[92] T cells help control interzonal migration and affinity maturation.[84] Because most somatic mutations destroy the BCR or lower its affinity, a large amount of apoptosis is present in the germinal center in addition to proliferation to provide substrates for mutations.

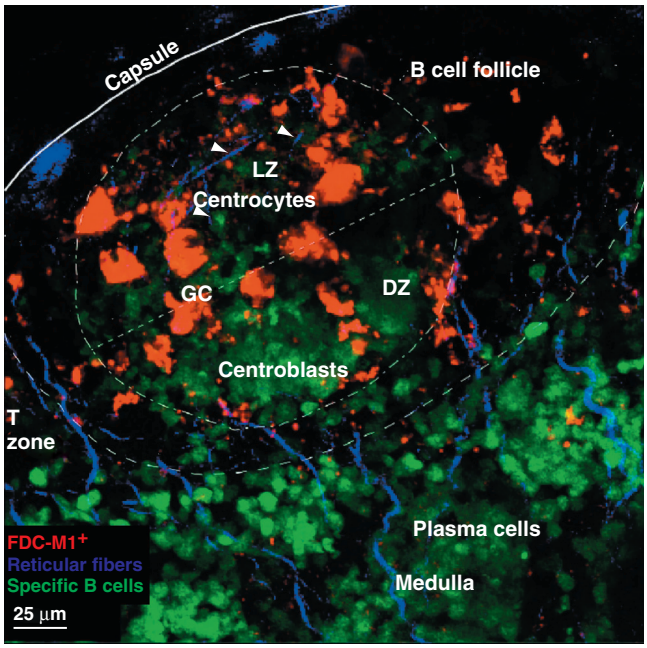

**Figure 18-6** Germinal center (GC) in living mouse lymph node. A GC was induced by vaccination after introduction of fluorescent antigen-specific B cells and antigen. Follicular dendritic cells were labeled with FDC-M1 antibody conjugated to a red fluorescent dye. Reticular fibers, which serve as antigen conduits into the follicle, are labeled *blue*. The GC is outlined and divided into a dark zone (DZ) containing aggregated centroblasts *(green)* and a light zone (LZ) containing loosely aggregated centrocytes, follicular dendritic cells (FDC-M1$^+$), and follicular T cells (not shown). The surrounding follicle is densely packed with bystander B cells (not shown), which often enter and traverse the LZ. *Green cells* in the medullary region are plasma cells produced in the germinal center reaction. *(From Schwickert TA, Lindquist RL, Shakhar G, et al: In vivo imaging of germinal centres reveals a dynamic open structure.* Nature *446:83–87, 2007.)*

## TERTIARY LYMPHOID TISSUES ARE GENERATED AT SITES OF CHRONIC INFLAMMATION

Tertiary lymphoid tissues resemble secondary lymphoid tissues in many respects but are formed in the adult in response to chronic inflammation in locations where such tissues do not exist in steady-state conditions. The induction of tertiary lymphoid tissues can be compared with the formation of lymph nodes during normal development. Normal lymph node development involves the colonization of connective tissues in characteristic vascular nexuses by RORγt-dependent, CD4$^+$, lymphotoxin-positive lymphoid tissue inducer cells.[93] These cells use surface lymphotoxin and TNF to induce local stromal cells to express ICAM-1 and VCAM-1 and produce CCL19/21 or CXCL13, leading to development of lymph node stroma with a reticular fiber conduit system that is integrated into the developing lymphatic vessel system. Thus steady-state presentation of inflammatory cytokines plays a key role in this process. This normal process can also be recapitulated in the adult because chronic inflammation induces production of TNF and lymphotoxin in normal tissues, leading to the induction of stromal cells to form organized follicles and T cell zones within the inflamed tissues. Induction of stromal cells to produce CCL19/21 and/or CXCL13 is probably important in this process because transgenic expression of CXCL13 in ectopic locations in mice leads to the formation of fully developed B cell follicles in these tissues.[94] Thus B cells may have a particular capacity to induce tertiary lymphoid tissues. The efficacy of anti-TNF therapies in autoimmune disease may relate to the suppression of such tissues.[95]

Tertiary lymphoid tissues are often associated with autoimmune diseases (including rheumatoid arthritis) and the local infiltration of naïve T cells in an area with high concentrations of tissue-specific self-antigens, and innate stimulation may promote progression of disease by recruiting new T and B cell specificities into the autoimmune process.[96] Breaking this cycle may be a key target of anti-cytokine and

anti–B cell therapies that have been remarkably effective and are discussed in later chapters.

## FIVE MAJOR TYPES OF EFFECTOR T CELLS

$CD8^+$ effector T cells are generally cytotoxic and involved in killing of infected cells. $CD8^+$ T cell responses can be initiated without the help of $CD4^+$ T cells, but CD4 T cell help is required for effective $CD8^+$ T cell memory.[97] Important transcription factors for effector CD8 T cell differentiation are Tbet and eomesodermin.[98] Three major types of effector $CD4^+$ T cells are recognized (see also Chapter 12). The first defined axis for CD4 T cell differentiation was between IFN-γ–producing T cells expressing the master transcription factor Tbet and IL-4–producing T cells using the master transcription factor GATA3.[99] The IFN-γ–producing cells are referred to as *Th1 cells*, which help inflammatory cytotoxic T cell and macrophage responses, and the IL-4–producing cells, called *Th2*, help anti-parasitic B cell responses, leading to IgE production and eosinophilic infiltration. The major cytokines that initiate Th1 responses are IFN-γ and IL-12 in the absence of IL-4, whereas IL-4 is the major cytokine that initiates the Th2 program. Recently it has been appreciated that a third type of effector T cell produces IL-17 and is important in many inflammatory diseases. Differentiation of these Th17 cells requires the nuclear hormone receptor RORγt.[100] The cytokine conditions that lead to development of Th17 cells are transforming growth factor (TGF)-β plus IL-6, or IL-1β with IL-23 for maintenance.[101] The contribution of TGF-β places Th17 cells on the same axis with induced regulatory T cells (Tregs), with the deciding factor being the presence of IL-6 or IL-1β to favor Th17 over Treg induction.[102] Th17 cells are highly pro-inflammatory T cells that trigger recruitment of neutrophils to combat extra-cellular bacterial infections. The generation of gut-associated Th17 cells in mice has been linked to a single species of segmented filamentous bacteria.[103] The presence of the commensal bacteria improves the clearance of intestinal pathogenic bacteria that require a Th17 response, but it also leaves the host more susceptible to autoimmune arthritis.[104] The most recently recognized Th lineage is the Tfh cells, which share the expression of the Bcl-6 transcription factor with germinal center B cells. The signature cytokine of Tfh cells is IL-21, which is critical for promoting B cell differentiation.[105]

## CONCLUSION
